Abstract

During last decades, the constant evolution of the construction systems has led to the possibility of carrying out increasingly complex architectural project. Among the wide range of construction systems, concrete thin corrugated-edge shells stand out for their relevance. In this paper, the mechanical behaviour of thin concrete corrugated-edge shell inspired by Nervi's Flaminio dome has been analysed in detail, considering different load configurations (self-weight, uniform vertical pressure and antisymmetric vertical load) and constrains (pure membrane and displacements restrained boundary conditions). Non-linear static analysis has been performed to assess the vertical load-bearing capacity of the corrugated-edge shell considering Concrete Damaged Plasticity (CDP) constitutive model and linear and non-linear buckling analyses have been carried out to evaluate the effects of the corrugation on buckling behaviour. The results obtained from linear and non-linear analyses have been compared with those obtained for a concrete thin smooth-edge shell having the same geometric global characteristics. The comparison

16 17 18 **1. Introduction** 19

20
21 Thin concrete shells constitute a paramount illustration of how theory and
22
23 practice are encountered. The use of concrete shells started at the beginning
24
25 of the XX century simultaneously with concrete technology development,
26
27 particularly for special purpose buildings such as gas tanks and thin-walled
28
29 domes. The theory foundations were laid by numerous scholars in the latest
30
31 part of XIX century [1], lately by [2]. Between the late 30s and 60s of
32
33 XX century, shell construction lived its most spreading period, due to the
34
35 cheap workforce and the use of wood and pneumatic formwork. Usually, they
36
37 were built for large roofs, silos for powder materials, reservoirs and tanks
38
39 for liquids, dams, chimneys, and cooling towers. The superior aesthetics
40
41 and the ability of such structures to span large spaces avoiding intermediate
42
43 support made this solution a very popular one. Besides, from a Structural
44
45 Mechanics point of view shell structures are characterized by high strength-
46
47 to-weight and stiffness-to-weight ratios. In pursuing the most effective shape
48
49 accounting for both mathematical and mechanical solutions and construction
50
51 feasibility, the most noteworthy designers were Eduardo Torroja in Spain,
52
53 Felix Candela in Mexico, Pier Luigi Nervi in Italy and Heinz Isler in Germany.
54
55 A look into the attitude of that time could be given looking at [3, 4]. Since
56
57 the 60s shell constructions have declined due to the upsurge of the formwork

9 21 price for curved surfaces, especially when compared with the development of
10 22 steel-spatial structures that can solve most of the issues for the long-spanning
11 23 building in a more cost-effective way.

14 24 Attention must be paid to the smoothness condition at the boundary. It
15 25 is well known that to ensure a pure membrane regime, the constraints must
16 26 be such that they do not perturb the stress distribution that would occur in
17 27 an indefinitely extended membrane. To that aim, restraints must act along
18 28 the meridian direction only. As a consequence, reaction must not have any
19 29 components in the normal direction to the shell. Other different boundary
20 30 configurations disturb the membrane state and lead to relevant bending mo-
21 31 ments concentrated nearby the edge. A well-established analysis techniques
22 32 of shell structure in scientific literature relies on the decoupling of membrane
23 33 and flexural regimes. A simplified analytical solution for the latter problem
24 34 is provided by [5]; another contribution is given by [6]. From a practical
25 35 point of view the perturbation occurring at the edge is unavoidable: in the
26 36 field of civil engineering structures, it is difficult to technically realize the
27 37 constraints needed for a purely membrane regime. Considering that bend-
28 38 ing effects are restricted to a limited zone near the edge, among the various
29 39 solutions adopted by designers, there are i) increasing the shell thickness or
30 40 ii) building a ring beam at the edge. When Nervi found himself involved
31 41 in the structural design of the Flaminio's dome for the Olympic Game in
32 42 1960, the contractors' demands were for a 60-metre roof for a stadium in
33 43 the Flaminio district in Rome to host boxing matches. The architectural de-
34 44 sign was commissioned to Annibale Vitellozzi and Nervi was involved in the
35 45 structural design in order to find an optimized shape for such a large span.

10 46 An innovative solution for limiting the bending moment near the edge was
11 47 proposed; it consisted in increasing the inertia of the shell section nearby
12 48 the edge adopting a smooth wavy shape without increasing the thickness.
13 49 Historical pieces of information about the building techniques are elucidated
14 50 in Nervi's books [7, 8] and [9]. Besides, SIXXI project has given new light to
15 51 the Italian concrete engineering school, of which Nervi was one of the pre-
16 52 eminent representatives (see [10]). The evidence of the recent refurbishment
17 53 undertaken by the Municipality of Rome is reported in [11]. The *Palazzetto*
18 54 *Flaminio*, is a sport facility, whose rooftop is a shallow spherical dome made
19 55 of low-reinforced concrete –patented by Nervi– referred to as *ferrocemento*.
20 56 It is supported by 36 equally spaced radial pillars, that are inclined to catch
21 57 the shell slope at the edge and lie on a circular ring foundation. The dome
22 58 is made by assembling the pre-cast individual pieces at ground level, then
23 59 they are singularly placed upon a scaffolding. Once all the pieces were in
24 60 place, a connecting casting was executed. From a qualitative point of view,
25 61 the corrugation built on the edge of the shell draw to two major structural
26 62 enhancements:

- 27 63 • firstly, the behaviour improves the membrane regime and reduces the
28 64 bending effect at the edge. Corrugation provides a stiffness increase
29 65 without the need of increasing the thickness. A simple model that
30 66 illustrates the idea behind this option can be found in [3];
- 31 67 • secondly, it is a well established fact that surfaces with free edges are
32 68 weak and subjected to inextensional deformation, *i.e.* the surface bends
33 69 without evoking significative strains in the middle surface. A complete
34 70 mathematical description of this phenomenon is given in [1], while some

Figure 1: (Above) View of the dome during in-between stages of construction, and of the scaffolding system used to build it. (Below) View of the completed dome.

71 remarks about it can be found in [12].

72 A framework of theory of shells is given in [2, 13–15]. A deep study about
73 the behaviour of concrete made shells is reported in [16, 17, 12, 17, 18]. Par-
74 ticular attention about instability phenomena in concrete shells is drawn in
75 [19]. The attention for such aspects are highlighted in the European design
76 recommendations [20]. Finally, a thorough coverage about construction de-
77 tails for concrete shell can be found in [21–23]. [24] reports a parametric
78 analysis concerning the role of corrugation in improving the seismic resis-
79 tance of vaults and domes, inspired by Eladio Dieste’s works of architecture.

10 80 Attention to purely compressed shells is highlighted in [25].

11 81 This study addresses the effect of boundary conditions on shells be-
12 82 haviour, as it is well-known that different boundary conditions lead to differ-
13 83 ent stress distributions. Besides, the effect of the combination of boundary
14 84 conditions and different edge geometry is highlighted. Moreover, a detailed
15 85 analysis is presented for the design of the edge and of the supports, since dif-
16 86 ferent restraint conditions may affect the buckling ultimate load. This aspect
17 87 should carefully be tackled, because such kind of structures are really thin in
18 88 comparison with the span, and the assessment of the buckling behaviour is
19 89 an uttermost part of the design process [26]. The correct evaluation of static
20 90 stresses serves as the backdrop of a buckling analyses, as it has been stressed
21 91 in [27] and [28] especially with regard to sudden collapse.

22 92 Specifically, the case of a wavy-corrugated edge shell is exploited. In
23 93 Section 2 the geometrical representation of the corrugated edge shell is intro-
24 94 duced in such a way that mathematical parametric equations are given. In
25 95 Section 3 the linear elastic structural behaviour is addressed with respect to
26 96 three load cases: pressure load, self-weight load and antisymmetric vertical
27 97 load. Furthermore, two boundary conditions are considered: pure membrane
28 98 boundary condition and fully restrained displacements. The discussion pro-
29 99 vides a comparison with a geometrically comparable spherical dome. In
30 100 Section 4 such a comparison is carried out with regard to the ultimate load
31 101 bearing capacity in the plastic range. In Section 5 the effects of corrugation
32 102 on buckling behaviour is evaluated. Finally, Section 6 provides some con-
33 103 cluding remarks about the structural improvement of shell edge corrugation.

104 **2. Dome geometry**

105 In this section, a mathematical description of a wavy-edge surface is pro-
106 vided. The shape is inspired by Nervi's Flaminio dome in Rome. Equations
107 for edge-corrugated surface are described in [29]; in the following discussion,
108 a more adherent shape to the original one is presented, where the merid-
109 ian passing through the support is perfectly spherical. This update allows
110 highlighting the membrane state of the shell. The adopted spherical polar
111 reference system is depicted in Fig. 2, where r is the radial distance from the
112 pole, ϑ is the colatitude angle (the complement to the latitude angle) and φ
113 the longitude angle. Therefore, a point P in a 3-D space is uniquely identi-
114 fied by its spherical coordinates (r, ϑ, φ) . A parametric representation of the
115 corrugated-edge spherical surface can be given by introducing a parametriza-
116 tion of its radius. Introducing the equation for a spherical shell, whose radius
is R_0 , the parametric equations are:

Figure 2: Spherical coordinate system.

117

$$118 \quad \begin{cases} x = R_0 \sin \vartheta \cos \varphi \\ y = R_0 \sin \vartheta \sin \varphi \quad \vartheta \in [0, \pi/2], \varphi \in [0, 2\pi). \\ z = R_0 \cos \vartheta. \end{cases} \quad (1)$$

119 Starting from Eq. (1) by squaring and summing up both sides, parameter
120 ϑ and φ can be eliminated and the resulting *implicit* representation of the
121 spherical surface is obtained:

$$122 \quad x^2 + y^2 + z^2 - R_0^2 = 0. \quad (2)$$

123 Now, recalling that the radial distance r is given, in terms of Cartesian
124 coordinate, by

$$125 \quad r = \sqrt{x^2 + y^2 + z^2}, \quad (3)$$

126 an *explicit* representation of the spherical surface results: $r = R_0$.

127 This formulation is used to introduce corrugation on the surface. It is
128 worth noting that in the case of a spherical shell, the radius r is constant
129 and does not depend on the coordinates, whereas in the case of a wavy shape,
130 the radius changes periodically depending on the coordinates ϑ, φ . For such
131 kind of surface, the radius will be $r = r(\vartheta, \varphi)$; besides, one could introduce
132 the corrugation as a perturbation added to the constant radius R_0 of the
133 sphere:

$$134 \quad r = R_0 [1 + f(\vartheta)g(\varphi)]. \quad (4)$$

135 In Eq. 4 the perturbation is composed by two elements: the first one is
136 $f(\vartheta)$ that controls at which colatitude angle the perturbation starts (i.e. the

Table 1: Geometry of Flaminio's Dome in Rome

span [m]	radius [m]	rise [m]	thickness [cm]
58.5	48.5	5.8	20

opening angle ϑ_0), the second one relies on longitude angle φ and controls the shape of the parallels. In order to get a cyclic symmetry on the surface, function $g(\varphi)$ must be periodic; consequently an appropriate choice to obtain a smooth repetition by a number of waves equal to n is:

$$g(\varphi) = \cos(n\varphi) \quad (5)$$

Function $f(\vartheta)$, which controls the perturbation of the radius along the meridian with reference to that of a perfect sphere, R_0 , can be chosen in several ways. A possible choice is:

$$f(\vartheta) = aH(\vartheta - \vartheta_0) \left(\frac{\vartheta - \vartheta_0}{\vartheta_f} \right)^2. \quad (6)$$

Where a is a parameter controlling the amplitude of the perturbation, ϑ_0 is the colatitude angle where the perturbation begins, ϑ_f is the colatitude angle corresponding to the surface edge and $H(\vartheta - \vartheta_0)$ is the Heaviside's step function defined as:

$$H(\vartheta - \vartheta_0) = \begin{cases} 1, & \text{if } \vartheta \geq \vartheta_0 \\ 0, & \text{if } \vartheta < \vartheta_0. \end{cases} \quad (7)$$

The role of $H(\vartheta - \vartheta_0)$ is to switch on the radius perturbation in correspondence of the angle ϑ_0 , namely the colatitude angle at which such perturbation

153 originates. Summing up all these ingredients, the following expression for the
154 dome radius is proposed:

$$155 \quad r = R_0 \left\{ 1 + \frac{a}{2} H(\vartheta - \vartheta_0) \left(\frac{\vartheta - \vartheta_0}{\vartheta_f} \right)^2 [1 - \cos(n\varphi)] \right\}. \quad (8)$$

156 The main advantage of this formulation is that the amplitude of corrugation
157 at the dome edge can be easily controlled. For the undulated part of the
158 shell, the radius expression is:

$$159 \quad r = R_0 \left\{ 1 + \frac{a}{2} \left(\frac{\vartheta_f - \vartheta_0}{\vartheta_f} \right)^2 [1 - \cos(n\varphi)] \right\}. \quad (9)$$

160 So, the function describing the undulated shape of the edge varies between
161 two extrema: for $\varphi = \frac{2k\pi}{n}$ ($k \in \mathbb{N}$) one obtains:

$$162 \quad r_0 = r \left(\varphi = \frac{2k\pi}{n} \right) = R_0, \quad (10)$$

163 while for $\varphi = \frac{(2k+1)\pi}{n}$ the result is:

$$164 \quad r_1 = r \left(\varphi = \frac{(2k+1)\pi}{n} \right) = R_0 \left\{ 1 + a \left(\frac{\vartheta_f - \vartheta_0}{\vartheta_f} \right)^2 \right\}. \quad (11)$$

165 Let h be the maximum amplitude of corrugation at the edge for $\vartheta = \vartheta_f$; then
166 $h = (r_1 - r_0)/2$. To set this amplitude h of the cosine curve to an assigned
167 value, it has to be either:

$$168 \quad 2h = a \left(\frac{\vartheta_f - \vartheta_0}{\vartheta_f} \right)^2 \quad \text{or} \quad a = 2h \left(\frac{\vartheta_f}{\vartheta_f - \vartheta_0} \right)^2. \quad (12)$$

169 Returning now the example problem, the dimension of the Nervi's dome are
170 listed in Table 1; a comprehensive reference source for the survey of dome
171 dimensions is [30].

Figure 3: Plot of the cross-sections of the corrugated shell equations with Heaviside's function for three selected values of the longitude angle producing the maximum perturbation (blue dotted curve), zero perturbation (black curve) and intermediate perturbation (red dashed curve). These values of the parameters have been adopted: $R_0 = 1$, $a = 0.6$, $n = 36$, $\vartheta_0 = \frac{\pi}{6}$, $\vartheta_f = \frac{\pi}{5}$. Dimensionless coordinates have been used, by adopting the ratio between the actual values and the radius.

Figure 4: (left) Plot of the corrugated shell surfaces $r(\vartheta, \varphi)$ with Heaviside's function. These values of the parameters have been adopted: $R_0 = 1$, $a = 0.6$, $n = 36$, $\vartheta_0 = \frac{\pi}{6}$, $\vartheta_f = \frac{\pi}{5}$; (right) a magnified part of the dome, where the selected meridians are highlighted.

172 3. Evaluation of structural behaviour

173 It has been assumed that the dome is made of C20/25 reinforced concrete.
 174 The material behaviour is analysed only with regard to the linear-elastic part

1
2
3
4
5
6
7
8
9
10 of constitutive behaviour, hence, plasticity is disregarded in this Section.
11
12 Density γ is assumed to be 2500 kg/m³, Young's modulus is 30 GPa, and
13
14 Poisson's coefficient is 0.2. Furthermore, for sake of simplicity the RC is
15
16 always assumed to be uncracked, and time depending effects (*fluage*) are not
17
18 taken into account. Ref. [31] explains the special construction techniques
19
20 adopted by Nervi, and their application in some major Nervi's works and
21
22 how *ferrocemento* made structure can now be refurbished with reference to
23
24 two buildings.

25 The investigated dome analyses are carried out with different boundary
26
27 conditions, namely:

- 28 1. pure membrane boundary conditions: supports restrain displacements
29 only along the tangent direction. Rotations are allowed (see Fig. 5 (a)).
30
31
- 32 2. displacements fully restrained: the displacements along the x , y and
33
34 z directions are restrained. Rotations are allowed (see Fig. 5 (b)). In
35
36 this case, flexural effects are not negligible.
37

Figure 5: Adopted boundary conditions: (a) pure membrane; (b) fully restrained displacements.

190 The constrains are discretely applied on the 36 supports, so the edge between
191 two subsequent supports is free.

192 Structural behaviour in the two different boundary conditions has been
193 compared considering the two proposed shapes of the dome (the smooth and

1
2
3
4
5
6
7
8
9 194 the corrugated one). Thus, several load-cases (uniform normal pressure, self-
10 weight and antisymmetric vertical load) are addressed in order to compare
11 195 weight and antisymmetric vertical load) are addressed in order to compare
12 196 comprehensively the structural improvement provided by the corrugation at
13 197 the edge with respect to the smooth shell. The adopted FE model has 30564
14 198 8-nodes shell elements.

15
16
17
18
19 199 A simplified structural analysis of Nervi's dome has been already carried
20 200 out in [32], but without considering edge-corrugation; besides a different
21 201 opening angle has been assumed in the above-mentioned reference, which,
22 202 however, does not seem to agree with the architectural blueprints reported
23 203 in [30].

24 204 *3.1. Pressure load*

25
26
27
28
29
30
31 205 The structure is loaded by a uniform external normal pressure q_0 whose
32 206 magnitude is 5 kPa, applied inwards to the whole surface. Since the extension
33 207 of the shell is such that its rise to span ratio makes it rather shallow, it is
34 208 possible to approximate the self-weight load condition with such pressure.
35 209 This approximation allows tackling the problem of edge-corrugated shells
36 210 in an easier framework. Nevertheless, it constitutes a significant load-case
37 211 for pressurized vessels or maritime applications. Let N_φ and N_ϑ be the
38 212 membrane forces acting in the meridional and parallel directions. The stress
39 213 σ_ϑ and σ_φ are:

$$40 \quad 41 \quad 42 \quad 43 \quad 44 \quad 45 \quad 46 \quad 47 \quad 48 \quad 49 \quad 50 \quad 214 \quad \sigma_\vartheta = \frac{N_\vartheta}{t}, \quad \sigma_\varphi = \frac{N_\varphi}{t}. \quad (13)$$

51 215 Where t is the shell thickness, whose value is constant and equal to 0.20 m.
52 216 The numerical outcome of the analyses are presented in terms of membrane
53 217 stresses, σ_ϑ and σ_φ . The former represents the stress along the meridian

1
2
3
4
5
6
7
8
9
218 direction and the latter one the hoop stress. All numerical results related to
10
11 stress are presented in dimensionless form: stress value are divided by the
12
13 applied external pressure $q_0 = 5$ kN, while the angular position is given in
14
15 the dimensionless form ϑ/ϑ_f , where ϑ_f is the colatitude value corresponding
16
17 to the position of the edge, which is assumed to be the same in all considered
18
19 cases. Fig. 7 shows an example of the reaction forces for both shapes of the
20
21 shell in pure membrane conditions.

22
23 A common drawback occurs when shell stresses are evaluated in a re-
24
25 strained node, because of the chosen discrete boundary conditions at the
26
27 edge, which produces stress singularities. This issue is well-known in the
28
29 frame of FE analyses with shell elements [33]. Fig. 8 (left) shows the distri-
30

52 Figure 6: Load cases.

53
54
55

62
63
64
65

1
 2
 3
 4
 5
 6
 7
 8
 9
 230 not depend on boundary conditions if the dimensionless colatitude angle is
 10
 231 less than 0.75, and the four curves practically coincide. The aforementioned
 12
 232 notation will be used henceforth in all the analysed load-cases. For colati-
 14
 233 tude values larger than 0.75, the curves for the pure membrane example are
 16
 234 not significantly affected by a change of shape, whereas, for the restrained
 18
 235 displacement example the corrugated-edge shape presents a significant re-
 20
 236 duction of the stress in comparison with the smooth shape nearby the edge.
 22
 237 Similar considerations can be made for Fig. 8 (right), that shows σ_φ/q_0 ; here
 24
 238 indeed, the effect of stress decreasing due to edge-corrugation is evident in
 26
 239 both constrained displacements and pure membrane boundary conditions.

28
 29 Let M_ϑ be the section moment (which is dimensionally expressed as the
 30
 241 ratio moment/thickness, thus being homogeneous to a force) along the ϑ
 32
 242 direction and M_φ be the section moment along the φ direction. The output
 34
 243 is shown in Fig. 9 in dimensionless form, by dividing the relevant values by
 36
 244 a constant M_0 equal to 5000 kN.

38
 245 Fig. 9 (left) shows M_ϑ/M_0 : the pure membrane behaviour is granted
 39
 246 until ϑ/ϑ_f reaches the value 0.8, apart from the case of corrugated-edge and
 41
 247 restrained displacements boundary conditions, where the behaviour deviates
 43
 248 from pure membrane already for values close to 0.6. Beyond these values
 45
 249 the flexural effect is not negligible. For both cases the edge-corrugated shape
 47
 250 yields a reduction of nearly one-half of the bending moment values at the
 49
 251 edge with respect to the smooth shell.

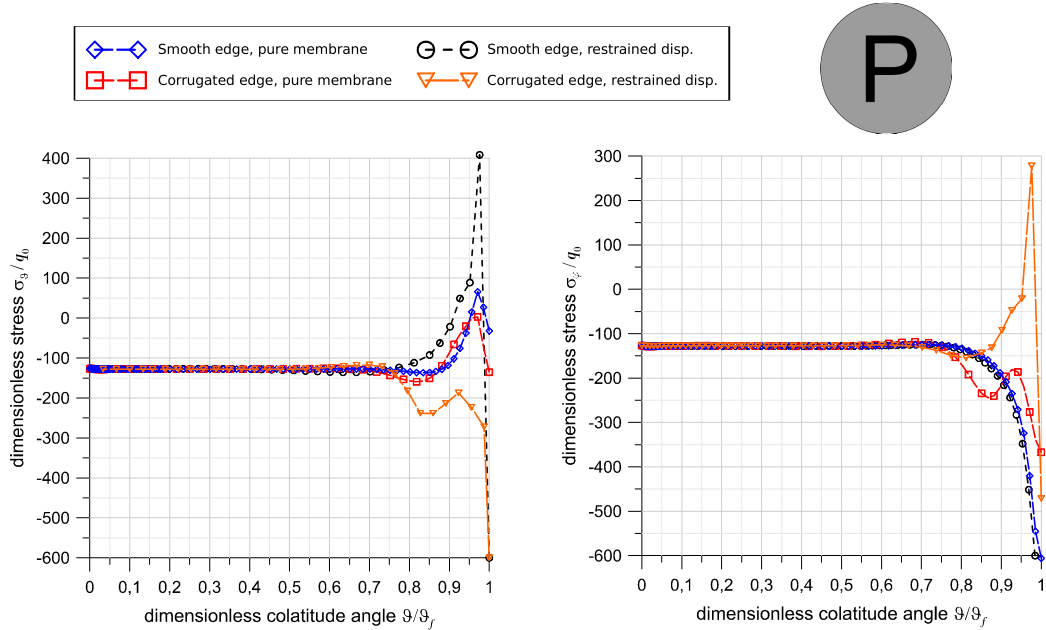

51
 252 Fig. 9 (right) shows M_φ/M_0 ; the pure membrane behaviour stands until
 53
 253 ϑ/ϑ_f reaches a value of about 0.7; beyond that value the bending effect is
 55
 254 relevant. The effect of the shape change at the edge is less relevant than

1
2
3
4
5
6
7
8
9
10 255 for the case of M_ϑ , as expected for the analysed shape, which is mainly
11 256 corrugated along the meridian. Nonetheless, there is a clear change in the
12
13 sign of the bending moments.

3.2. Self-weight load

The most relevant load-case for concrete domes is the self-weight load, hereby computed using the standard practice and design density value. Fig. 10 shows the distribution of σ_θ/q_0 for the analysed four cases. Again, the behaviour does not depend on the boundary condition if the dimensionless colatitude angle is less than 0.75. Beyond such value, no advantages are provided by corrugation of the edge, both in the case of pure membrane and restrained displacements boundary conditions.

The corrugated-edge shell stress curve outlines an inversion from compressive to tensile values close to the edge, but vanishes in correspondence to the edge. On the contrary, for such effect the restrained displacements case the

1
 2
 3
 4
 5
 6
 7
 8
 9 stress is always on compressive, even on the nearby support. Different con-
 10 siderations can be made for Fig. 10 (right), that shows σ_φ/q_0 ; the membrane
 11 state here is reliable until ϑ/ϑ_f reaches 0.6; indeed, the edge-corrugation
 12 does not improve significantly the hoop stresses, it rather worsens the stress
 13 concentration in the case of restrained displacements boundary condition.
 14 Fig. 11 (left) shows M_ϑ/M_0 ; the pure membrane behaviour stands until ϑ/ϑ_f
 15 reaches the value 0.6. From that point on significant bending moments oc-
 16 cur. While for the pure membrane boundary condition the edge-corrugation
 17 does not provide remarkable improvements, in the restrained displacements
 18 case there is a noteworthy reduction of the bending moment values at the
 19 edge with respect to the smooth shell. Fig. 11 (right) shows M_φ/M_0 ; the
 20 pure membrane behaviour is confirmed until ϑ/ϑ_f reaches the value 0.7. As
 21 previously stated in Sec. 3.1, and as expected, the effect of a shape change
 22 at the edge is less relevant than for the case of M_ϑ , apart from the case of
 23 pure membrane boundary condition.

284 3.3. Antisymmetric load

41 It is of interest in practical design to carry out extensive analyses of domes
 42 subjected to non symmetrical loads: for instance, wind load and special com-
 43 bination involving snow load should be carefully considered. The structure
 44 will be now analysed under an antisymmetric vertical load, *i.e.* a distributed
 45 load applied only on a semi-cap, whose magnitude is 5kN/m^2 (see Fig. 6).
 46 Due to the lack of symmetry of the problem, results will be shown along
 47 three different meridians, named *A*, *B*, and *C* corresponding to longitude
 48 angles φ equal to respectively of $\pi/2$, $3/4\pi$, and π , (see Fig. 12) this time
 49 considering that angular coordinate ϑ takes values between $-\vartheta_f$ and ϑ_f , al-

Figure 10: Self-weight Load - Stress components σ_θ (left) and σ_ϕ (right) along a meridian passing through a support.

294 lowing the effect of the load to be read in both the loaded and unloaded parts.
 295 The same figure also depicts the loaded portion of the shell. Thence, merid-
 296 ian A is symmetrically loaded for the whole length, meridian B is loaded
 297 only in the second quadrant and meridian C is loaded anti-symmetrically.
 298 Fig. 13 (left) shows the membrane stress σ_θ for meridian A , whose behaviour
 299 is as expected perfectly symmetrical. The behaviour does not depend on
 300 the boundary condition for dimensionless colatitude within ± 0.8 and the
 301 four curves practically coincides. Beyond ± 0.8 , only the curve for the re-
 302 strained displacements condition in the corrugated-edge shell, the stress re-
 303 mains compressive, whereas the other three curves show tensile stresses near
 304 the edge, with possible crack issues if no tension material were considered.

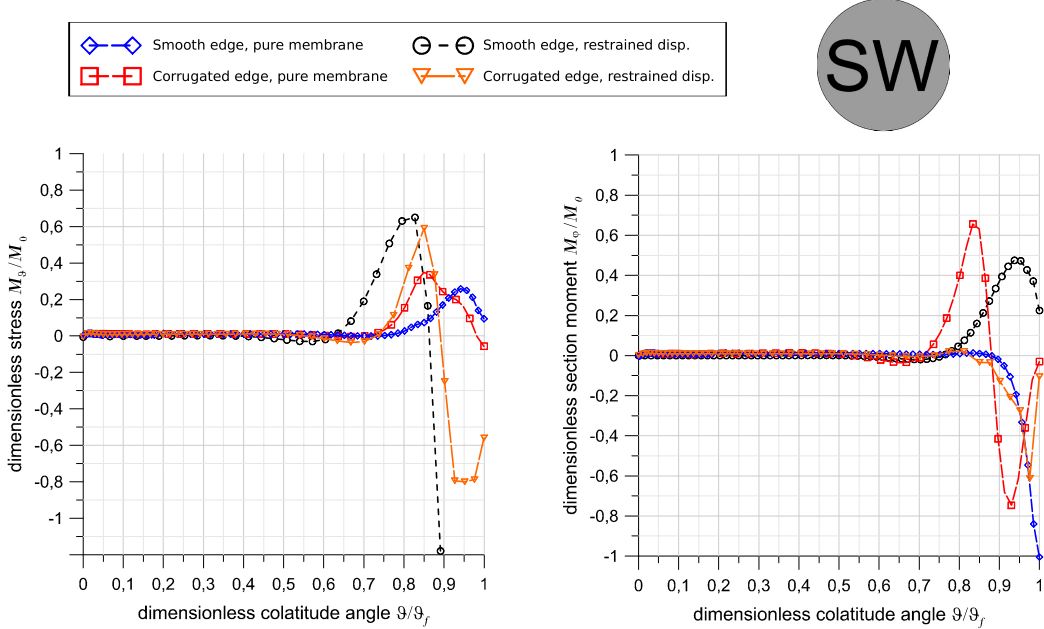

Figure 11: Self-weight Load - Section moments M_θ (left) and M_φ (right) along a meridian passing through a support.

305 Fig. 13 (right) shows the membrane stress σ_φ for meridian A . The perfectly
 306 symmetrical behaviour, is independent from the shape of the shell and from
 307 its boundary conditions and follows a pure membrane regime within the val-
 308 ues of dimensionless colatitude angle equal to ± 0.8 . Beyond ± 0.8 , only the
 309 curve for restrained displacements condition and corrugated edge shell shows,
 310 this time, a relevant tensile stress nearby the constrains.

311 Fig. 14 (left) shows the membrane stress σ_θ for meridian B . The effect
 312 of the load is noticeable for ϑ/ϑ_f between 0 and 1 and particularly intense
 313 on the edge; on the other half it is practically irrelevant except near the con-
 314 straint, where some minor stress peaks are detected. Fig. 14 (right) shows the
 315 membrane stress σ_φ for meridian B . The effects due to the load are the same

Figure 12: Upper view of the dome, where the positions of the selected meridians for the anti-symmetric load case are highlighted.

as discussed before and shape and kind of constraints do not substantially affect the stresses.

Fig. 15 (left) shows the membrane stress σ_{ϑ} for meridian C . Again, the effect of the load is remarkable for ϑ/ϑ_f between 0 and 1, while on the opposite side it is practically negligible except near the constraint, where stress peaks are localised. Fig. 15 (right) shows the membrane stress σ_{φ} for meridian C . The situation is the same as discussed before and no substantial differences can be observed between the four curves.

Fig. 16 (left) displays M_{ϑ}/M_0 distribution along meridian A . The pure membrane behaviour is confirmed until ϑ/ϑ_f reaches values ± 0.8 . Outside this range the bending effect is relevant and peaks are localized on the con-

Figure 13: Anti-symmetric Load - Stress components σ_θ (left) and σ_φ (right) for a meridian A passing through two supports located at $\varphi = 90^\circ$.

327 straints for all the four curves, especially for the corrugated-edge shell in pure
 328 membrane boundary condition. Fig. 16 (right) shows M_φ/M_0 . The pure
 329 membrane behaviour stands in the range $-0.8 < \vartheta/\vartheta_f < 0.8$, then bending
 330 effects are remarkable. The effect of boundary conditions at the edge is not
 331 relevant at the edge. On the contrary, corrugation modifies considerably the
 332 moment distribution.

333 Fig. 17 (left) shows M_ϑ/M_0 along meridian B . The pure membrane be-
 334 haviour is limited to ϑ/ϑ_f ranges of $[0.3, 0.7]$ and $[-0.7, -0.3]$. Outside these
 335 intervals the bending effect is relevant. Peaks of section moments are ob-
 336 served in apex because of the sudden change of load distribution. The four
 337 curves do not show significant change due to shape. Fig. 17 (right) illustrates

338 M_φ/M_0 distribution. Along the same meridian B the behaviour is similar to
 339 the previous, since pure membrane behaviour is enclosed in narrow intervals
 340 and bending effects are not negligible. Again, no enhancement is provided
 341 by corrugated shape.

342 Fig. 18 (left) shows M_ϑ/M_0 distribution. Lack of symmetry is evident
 343 and pure membrane behaviour is limited to minor part of the meridian.
 344 Mainly the bending effects are relevant, with section moment peaks located
 345 around the apex and near the edge. The corrugated edge shell shows highly
 346 localized bending moment at the edge in both boundary conditions. Finally,
 347 Fig. 18 (right) reports M_φ/M_0 distribution. Along the same meridian C the
 348 pure membrane behaviour is recognisable in a wider range of ϑ/ϑ_f , except

for the smooth edge with restrained displacements where the bending effect starts earlier. Large values of bending moment are observed at the edge, especially in the loaded part of the shell.

4. Assessment of load-bearing capacity by means of nonlinear analysis

To evaluate the influence of corrugated edge in the vertical load-bearing capacity of the dome, a non-linear static analysis has been performed. The constitutive law of the material adopted is based on the Concrete Damage Plasticity (henceforth CDP) law, that has been first developed by [34] and later improved by [35]. CDP is a plasticity and-damage-based model that

Figure 16: Anti-symmetric Load - Section moments M_θ (left) and M_φ (right) for a meridian A passing through two supports and located at $\varphi = 90^\circ$.

359 takes into account cracking in tension and crushing in compression for defin-
 360 ing failure mechanisms.

361 The model is geometrically isotropic but is able to take into consider-
 362 ation the tensile and compressive behaviour independently, using different
 363 parameters which regulate plasticity and damage. Fracture is implemented
 364 according to concrete-like *smearred crack* model with fixed crack orientation,
 365 that tackles Hilleborg's theory of fictitious crack [36], thus governed by a
 366 strain softening behaviour and Mode I fracture energy. The latter is in-
 367 tended to regularize the mesh dependency of the computational FE model
 368 due to damage and strain localization, in conjunction with the elements size,
 369 regarded as a characteristic crack band length for the material [37].

Figure 17: Anti-symmetric Load - Section moments M_θ (left) and M_φ (right) for meridian B , passing through two supports and located at $\varphi = 135^\circ$.

370 Model parameters and adopted values are reported in Table 2. In par-
 371 ticular: Ψ is the dilatancy angle; e ($0.1 \leq e \leq 0.3$) is the *eccentricity* that
 372 smooths the meridian section in proximity of the Drucker-Prager cone vertex
 373 to avoid convergence issues in the flow potential; f_{bo}/f_{co} is the ratio of biaxial
 374 compressive to uniaxial compressive yield stress, whose value is defined ac-
 375 cording to that suggested for concrete-like materials [34]; K_c ($0.5 \leq K_c \leq 1$)
 376 is the parameter that adapts the shape of the triaxial yield surface in such
 377 a way that in the deviatoric plane it varies from the classic Drucker-Prager
 378 circle for $K_c = 1$, to a Rankine-like triangle when lower values are assumed;
 379 ν is the viscosity parameter. The stress-strain curves for compression and
 380 tension implemented in the FE model are reported in Fig. 19, while Fig. 20

Figure 18: Anti-symmetric Load - Section moments M_θ (left) and M_φ (right) for meridian C , passing through two supports and located at $\varphi = 180^\circ$.

381 shows the related damage curves, which describe the evolution of the dam-
 382 age variables in tension and compression affecting the elasticity matrix. The
 383 structure has been subjected to its self-weight q_0 , regarded as the most rep-
 384 resentative load-case, then to an incremental vertical load $q = \lambda q_0$, where
 385 lambda is a load multiplier (≥ 1). The non-linear behaviour is assessed by
 386 increasing the vertical load q up to collapse. To highlight the influence of cor-

Table 2: Parameters of Concrete Damage Plasticity model

387 rugation, a comparison between the capacity curves obtained for the smooth
 388 and the corrugated edge shells is provided in Fig. 21. In the curves the dome
 389 apex is chosen as a control point, whose vertical displacement dz has been
 390 monitored. In the curves the displacement is normalized with respect to the
 391 initial vertical displacement dz_0 due to self-weight, as well as the vertical load
 392 q is normalized with respect to the self-weight q_0 , so that the load multiplier
 393 λ is directly reported in the graph. Since smooth and corrugated edge domes
 394 have different volumes, their total weights q_0S (where S stands for shell
 395 area), along with the relative initial vertical displacements dz_0 , are reported
 396 in Table 3. Due to convergence drawbacks, related to the concentration of
 397 damage at the supports the analyses stopped prematurely. Nevertheless, the
 398 subsequent considerations can be highlighted. The obtained curves show dif-
 399 ferences in terms of slope of the linear elastic branch. In fact, it is possible to
 400 notice that the corrugated edge dome exhibits a linear elastic behaviour for
 401 values of the load multiplier larger than the smooth dome, with an increase
 402 equal to about 1.6 times. This difference is due to the greater geometrical
 403 stiffness provided by the corrugation at the edge. This increase in stiffness
 404 can be also evaluated looking at the apex displacements at the end of the
 405 elastic phase: in the case of the smooth dome the apex displacement is about

1
2
3
4
5
6
7
8
9
406 1.8 times larger than that of the corrugated edge dome. Furthermore, the
10
407 corrugated edge dome shows a vertical load-bearing capacity greater than
11
408 the smooth edge dome. In both domes, the collapse is reached with the same
12
409 mechanism, where the damaged zones are concentrated in correspondence to
13
410 the supports, as reported in Fig. 22. The occurring of the same mechanism of
14
411 failure, but associated to different values of load multipliers suggests that the
15
412 larger geometrical stiffness due to corrugation at the edge plays an effective

414 5. Effect of corrugation on buckling behaviour

415 This section deals with the assessment of the edge-corrugated shell per-
416 formance in comparison with the smooth shape, with respect to instability
417 issues. The effects of bending stiffness increment in spherical shells towards
418 buckling has been envisaged in [38]. The presented analyses are inspired by
419 the works [39–41]. The theoretical critical load for a complete spherical shell

Figure 20: Damage curves: compression (left) and traction (left) branches.

420 has been widely treated in the scientific literature, among the several sources,
 421 [42] is selected as the preferred one.

422 The main problem when dealing with spherical shell instability issues is
 423 that the theoretical load is not reliable for design purposes; in fact, experi-
 424 mental campaigns carried out over the last century have widely proven that
 425 designers should adopt precautions against the actual ultimate load. This
 426 discrepancy is triggered essentially by geometry and material imperfections,
 427 as clearly elucidated by the eminent work of Koiter [43]. Recent studies
 428 about spherical shells buckling have been carried out making use of FE cal-
 429 culation, see for instance [44–46]. The American Code assessment procedure
 430 against instability is based upon [47, 48]. The method consists in employing
 431 several empirical *knock-down* factors that decrease the theoretical buckling
 432 load by globally taking into account the presence of: imperfections, creep,
 433 plasticity, cracking and, eventually, of reinforcements. To each of these ef-
 434 fects corresponds an appropriate partial factor. This method has a major

Figure 21: Capacity curve for the dome modelled with CDP.

drawback, *i.e.* it is too conservative and the ultimate load may result as low as 20 % of theoretical load, with a considerable increase of building costs. Research is ongoing on ascertaining a less conservative approach without jeopardising structural safety (see [49]). In this section, a non-linear instability analysis of the corrugated dome will be shown, taking into account only geometrical imperfections. In order to understand the effects of shell edge-corrugation towards instability, imperfections have been accounted in

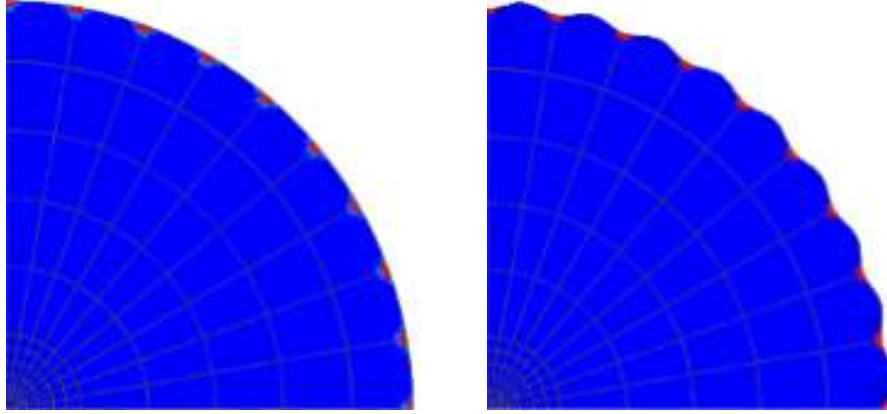

Figure 22: Damage zones highlighted for both domes (left): smooth edge (right): corrugated edge.

the form of eigen-shapes provided by a FE linear buckling analysis. The geometrical and mechanical properties used for the model are the same already employed throughout the previous Sections. This time, only the restrained displacements boundary condition has been employed at supports.

A finite strain 4-nodes shell element has been adopted for the post-buckling analysis [50], which has been carried out by means of Riks' arc-length incremental algorithm [51–53].

Hereafter, the analysed load-case is the dome self-weight, $q_0 = \gamma t$, where γ is the specific weight. Fig. 23 compares the first five buckling eigen-shapes for a smooth edge shallow dome (left) and for the corrugated-edge one (right). The contour plot depicts the displacement magnitude distribution upon the deformed shape. Table 4 reports the corresponding first five eigenvalues, highlighting the percentage difference in the third column. As shown, there is always an improvement in the critical load due to the edge-corrugation, which varies from 3.6% up to 6.0% for the fifth mode. It is noteworthy that the

1
2
3
4
5
6
7
8
9
10 457 presence of the corrugation breaks the symmetry coupling of eigenvalues in
11 458 the spherical case. Moreover, the increased stiffness of the corrugated edge
12
13 459 prevents the occurrence of instability nearby the edge, which is shifted to
14
15 460 higher modes. That is why the first three eigen-modes of the corrugated-
16
17 461 edge shell are far different from those of the smooth one.

18
19 462 Fig.24 shows the outcomes of non-linear stability analyses with descrip-
20
21 463 tion of post-buckling behaviour with regards to the cases of smooth spherical
22
23 464 dome (left) and corrugated-edge dome (right) for perfect ideal shapes (black
24
25 465 line) and imperfect real shapes (blue line). The presented curves are the
26
27 466 equilibrium path identified by means of an arc-length incremental procedure
28
29 467 in large displacements. Geometrical imperfections have been modelled for
30
31 468 both shells according to the respective first buckling mode-shapes scaled by
32
33 469 a factor of 0.1 and assumed as the undeformed initial geometry. As antici-
34
35 470 pated, y -axis reports the load-multiplier applied to the structure self-weight.
36
37 471 Regarding the smooth shell case on the left, the description of the ideal case,
38
39 472 *i.e.* with no imperfections, has encountered irrecoverable convergence issues,
40
41 473 probably due to the presence of a bifurcation equilibrium point, therefore
42
43 474 no critical load and no post-buckling mode have been evaluated. On the
44
45 475 other hand, the case of geometrically *imperfect* shell has been completely
46
47 476 exploited and both the buckling load and the post-buckling behaviour have
48
49 477 been clearly determined, the latter showing a snap-through response. Hence,
50
51 478 it is still possible to argue that the buckling load has consistently decreased
52
53 479 due to the imperfection introduced in the model with respect to the per-
54
55 480 fect case and further reduction is to be expected if the imperfection scaling
56
57 481 factor is amplified. Analogous comments can be outlined for the case of

Table 4: Eigenvalues of the linear buckling analysis

	smooth	corrugated	difference [%]
1 st	99.804	104.66	3.6 %
2 nd	99.804	104.67	3.7 %
3 rd	99.923	104.81	3.9 %
4 th	99.923	106.52	5.6 %
5 th	99.994	106.93	6.0 %

the corrugated-edge shell, which has been completely developed both in the case of perfect geometry and of imperfect geometry. Hence, it is possible to evaluate the effect of such an imperfection, in terms of a knock-down factor of about 0.60 on the critical load, but, even for the ideal case, it has been possible to point out a remarkable critical load reduction, about 35%, with respect to the first eigen-value determined via the linear procedure. Since the presented cases are based on geometrical imperfections modelled on the respective the first buckling mode-shapes, in this section no meaningful comparison is possible between smooth and corrugated-edge shells behaviours.

6. Conclusion

This paper addresses the effects of an edge shape modification on the structural behaviour of shallow spherical shells under discrete support boundary conditions. In particular, the introduced geometrical perturbation consists of a wavy co-sinusoidal corrugation applied nearby the supported bound-

1
2
3
4
5
6
7
8
9
10 497 ary, whose mathematical representation is given in Sec 2. The structural be-
11 498 haviour modification and possible improvement caused by this geometrical
12
13 499 perturbation have been evaluated from different points of view and concern-
14
15 500 ing several load scenarios and boundary conditions. Numerical analyses pre-
16
17 501 sented here support Nervi's insight of Flaminio stadium reinforced concrete
18
19 502 rooftop.

20
21 503 In Section 3 the linear elastic structural behaviour has been analysed with
22
23 504 respect to several typical load-cases under pure membrane and displacements
24
25 505 restrained boundary conditions. The comparison between the spherical and
26
27 506 the corrugated dome reports of a prevalent improvement for the pressure
28
29 507 load case and a less significative one for the self-weight load. On the whole,
30
31 508 the section moments for the corrugated shape denote a moderate reduction.
32
33 509 In the case of anti-symmetrical distributed load no major improvements are
34
35 510 observed, apart from a slight decrease in the stresses at supports. Ultimate
36
37 511 load bearing capacity has been compared in Section 4, taking into account
38
39 512 plasticity of reinforced concrete. This time the enhancement of the structural
40
41 513 performance has been clearly disclosed in terms of stiffness and collapse load.
42
43 514 Section 5 deals with the influence of the shape corrugation on buckling be-
44
45 515 haviour in linear and non-linear fields. Given the relevance of this problem
46
47 516 in thin-shell structures, the buckling behaviour will be studied more compre-
48
49 517 hensively in a forthcoming paper, to ascertain how the discussed geometry
50
51 518 affects the stability of such shells and to discuss a prospective corrugation
52
53 519 optimisation.
