# Hybrid Mesoporous and Microporous Materials Characterisation

Scientific Disciplinary Sector

FIS/01

PhD student:                                             MariaVitalia Tiddia

Coordinator of the PhD Programme:              Paolo Ruggerone

Supervisor:                                               Guido Mula

Final exam. Academic Year 2017-2018

Thesis defence: January-February 2019 Session

1

# Preface

This thesis is an account of the work carried out by the author at the Università degli Studi di Cagliari, Sardinia, in the PoroSiLab @ Dipartimento di Fisica and at the National Physical Laboratory in Teddington, between 2015 and 2018, under the supervision of Prof. Guido Mula (Università degli Studi di Cagliari), Dott. Rasmus Havelund and Prof. Ian Gilmore (National Physical Laboratory). No part of this work has been previously used for a thesis or a degree at this or any other university. The work of the authors is acknowledged in the text. A list of references has been included at the end of the manuscript. The majority of this thesis has been submitted and published as articles. A list of these appear in chronological order.

    Poster: Preparation of Polyaniline/Porous Silicon Hybrids for photovoltaic applications

# Acknowledgment (ringraziamenti)

Here we are at the end of this deadly-fantastic-disgusting-astonishing-exausting-endless-amazing adventure. Yes, this is what it is: a hotchpotch of every possible feeling. I am so grateful I've done with it now but without it I could never be the person I actually am.

First of all my thanks go to my supervisor Doc. Guido Mula. Without him I could have still been doing my 3rd year of university, working in an awful place just to pay some taxes. He is basically the best guide you can have if you get lost. So for this reason thanks a lot to him and to his wife Doc. Susanna Setzu who showed me what being a successful woman means!

Second big thanks goes to Professor Ian Gilmore who, falling in love with Sardinia, my land, met my supervisor Guido and introduced me to the possibility of joining is group at NPL to "conclude my PhD". It was fantastic to have the opportunity to carry out the majority of my research in your facilities. What a cracking place to work!

Thanks to all the people of NPL that supported me in these years and made me laugh when I wanted to dig a hole and jump in. A particular thanks goes to Rasmus Havelund, my supervisor at NPL and Ichiro Mihara that first introduced me to the Focused Ion Beam world; to Jean-Luc, Natalie, David, Matthias and Melissa that welcomed me as friends even knowing that I was just a PhD student and that I could not understand one world of their perfect spoken English.

To my parents, brothers and friends that always supported me even in my crazy-depressive moments during these 3 years.

Thanks Barry for tolerating me, walking with me on this adventurous path and be my biggest supporter.

Un enorme grazie va alle mie amiche Roberta, Emanuela e Valentina che mi ricordano sempre da che bellissimo posto provengo e che genuinamente (povere loro) sono contente di avere una amica scienziato!

Un ultimo e special Grazie a Mamma e Babbo, perche' se sono qui e' solo perche' mi avete fatto forte abbastanza e grazie Marco e Giuseppe perche' i fratelli sono come la Nutella, che mondo sarebbe senza!

*To those who are not here anymore……*

*Contents*

# *1 Introduction*

This thesis project is aimed at the study and characterisation of interfaces between organic and inorganic materials. The two classes of material are coupled together in order to develop hybrid systems and they are described in 2.2. The need for more accurate and explicit analytical solutions for hybrid material interfaces analysis and related novel experimental characterisation techniques derives from the potential of these complex interfaces for the development of new devices in a large variety of application fields such as optics and electronics [1][2].

## 1.1   State of the art

The research on hybrid material has been conducted using a multifaceted approach: from theoretical physics and chemistry [3] to various material and device characterisation methods [4].

The interest in hybrid materials has led to a significant research effort also through both academic and manufacturing research and development [4]. For the fabrication and characterisation of organic-inorganic devices, prototypes have to be built using a mixture of materials with properties tailored for a significant role in the scientific development and the instrumental uptake of these materials. These materials are the key ingredients necessary to provide resistance, flexibility, durability and good processability in electronic devices, industrial material and bio-applications [5]. The various organic and inorganic bulk materials can be obtained by using evaporation techniques, beam deposition [6][7] or inkjet printing [8][9], methods that allow simplified and faster production. The procedure of device preparation often generates structural defects [10], inhomogeneity in the deposition or in the filling degree (in case of the insertion of material in porous structures) [11]. Industries and research in general need to obtain information about the quality of the processes and about the structural nature of any final device. This characterisation is carried out by using several techniques having as common target the understanding of the variations induced by the fabrication process. Specifically, for applications as organic light-emitting diodes (OLED), photovoltaic cells and nanoparticles for drug delivery, the analysis of interfaces is a critical step for the further development of these systems [12][13].

Research on organic–inorganic devices requires the cooperation among research groups with different and complementary expertise. For this reason, this study involved a collaboration between Cagliari University and NPL. The aim was to resolve fundamental problems present in the porous silicon structure used in Cagliari University by utilising mass spectrometry expertise at NPL. This is an

example where two different fields can find a common way to interact about organic-inorganic hybrid devices.

This thesis research is undertaken to address the following challenges: a) the effect of the insertion of polymer in porous material via an electrochemical process, b) the analysis of the photocurrent generated by developing a hybrid p-n junction, c) the stability and the resistance added to the pristine material by the process and d) the definition of a protocol for mass spectrometry analysis of porous materials and buried interfaces. Two popular analysis techniques, electrochemistry and mass spectrometry, have been used to analyse the organic-inorganic hybrid materials and interfaces using different polymers and different inorganic substrates.

In chapter 1 and 2, the importance of hybrid materials and polymers will be discussed, underlining some of their characteristic and properties that can be exploited.

In sections 2.3 and 2.4, electrochemical and optical studies made on porous silicon grafted with a conducting polymer will be presented. Properties as the resistance to chemical corrosion by harsh basic solutions and the photocurrent generation will be studied and explained. The possibility to understand how the polymer is attached to the pore walls is investigated by mass spectrometry imaging. This technique requires refinement of measurement parameters for this class of materials, a study that has been implemented by using Si materials with similar composition and geometry although on a larger scale. To do this, in chapter 4 the use of focused ion beam (FIB) for milling the surface of a porous micrometric matrix and the cleaning procedure to recover the damaged polymeric component will be described. This method will be applied to other devices to highlight the effectiveness of this technique, in section 4.8. These studies provide the essential metrological foundation to address frontier issues in surface and nanoanalysis and extend the measurement capabilities of secondary ion mass spectrometry.

In the last chapter, a summary of all the analysis and future development will be presented.

## 1.2 Hybrid materials

Organic-inorganic hybrids are a relatively recent alternative choice in cases where it is required to have materials with new and unusual features [4]. This is related to their diphasic structures, leading to multifunctional materials [4]. For the most part, these structure are synthesized in low temperature processes allowing for variability even in the compound design [14]. Physics and chemistry play an important role in the fabrication and control of these structures, having complementary information useful for their preparation and for the control of their properties [15].

The combination of inorganic and organic components in one material to achieve improved properties is as old as history. Combinations of this nature were developed because of a shortage in the required material characteristics in the traditional choice of available materials, which could only be filled by merging two totally different single components. Applying this approach, one can find many examples in antiquity. One impressive case is the old dye Maya blue, which is a mixture of a clay mineral and the organic dye indigo, and shows remarkable high stability, which indigo alone does not [16]. This material is often considered one of the first hybrid materials [17] [18]. Another example is combining straw, an organic fibre, and clay as an inorganic matrix for house building. This mixture is solid, durable, non-toxic, and can be used in structural elements. In addition, it is a reasonably good thermal insulator and a thermal storage medium [19]. We would not really call this material a hybrid material in a scientific context, more realistically it would count as a composite material.

The challenge of combining organic and inorganic materials in a unique new material continued during the industrial era, for example in paints, by using $TiO_2$ as a pigment, suspended in a mixture composed of an organic solvent and surfactants [20]. While the concept of hybrid materials didn't exist at the time, since the beginning of the 20th century scientists were already noticing the potential for the use of polymers in this way. Clay, talc, and minerals have been added to polymers to improve resistance, durability and malleability modifying the melting point [21] [22]. "Hybrid" as a term to describe these structured materials has been introduced relatively recently in terms of materials innovation and advancement, in areas such as solar cells, fuel cells, strain sensors, biosensors and drug delivery systems [23–29]. Many modern materials we encounter in our everyday life, e.g. glass- and carbon fibers-reinforced polymers address our current view on the beneficial combination of two different materials that generate a novel compounds showing superior properties if compared to the characteristics of the pristine components [30] [31].

Different characteristics arise for the hybrids, depending on the strength of the bonds within the new materials. Hybrid composites are considered biphasic when the organic and inorganic phases are mixed on the nanoscale [4]. On that scale, the properties of the materials are not the sum of those of the individual components, but the inner interfaces also play a dominant role in the properties of the new structures [32] [33]. In other cases, the organic and inorganic phases are embedded and only weak bonds (hydrogen, van der Waals or ionic bonds) give the cohesion to the whole structure [34]. In further combinations, the two phases are linked together through strong chemical bonds (covalent or ion-covalent bonds). The organic component is generally considered more fragile due to a lower thermal stability with respect to the inorganic counterpart [15] [5].

The current definition of "Hybrid" materials is given by the IUPAC nomenclature as follows:

"A hybrid material is composed of an intimate mixture of inorganic components, organic components, or both types of component. Note: The components usually interpenetrate on scale of less than 1 μm" [35].

By using that definition, the idea of hybrid materials covers polymer blends at every scale, and many types of inorganic crystalline materials, giving a large range of possible uses. A description, often used by scientists in literature regarding hybrid material, is that they are made by a minimum two component materials, one organic and one inorganic, dispersed at the molecular level [34]. Following this definition, hybrid materials are a special case of composites showing a mixture of the different components on the molecular length scale [15].

In hybrid materials, even when the two components are transparent to a given wavelength range, the different components don't allow necessarily a high degree of transparency of the material. This is caused by the scattering of light that derives from the spatial dispersion of the various components with different refractive indices, in particular when the impinging light wavelength is comparable with the hybrid material dispersion length scale. In the case where this length scale is smaller than the light wavelength, the light scattering is minimized and the material can be considered transparent. Depending on the transparency degree, the added value of the high flexibility of fabrication processes for hybrids with respect traditional glasses has raised interest in the building of new optoelectronics devices from hybrid materials, for instance for their use in photolithographic processes [36]. The hybrid materials can be functionalized so that their chemical and physical properties can be tailored to an optimal interaction response to light, electrical and thermal stimulations: for example waveguides, photodetectors, gratings and micro optical devices can be built from these classes of materials [37–39].

Another relevant field where hybrid materials are being widely used is the electronic industry, given the continuous need to improve integrated circuits performance while reducing the size of components through scaling [40]. In this field, lithography tools and photoresist materials are approaching their physical limits with standard materials. To be able to continue, the scaling process will require the introduction of new materials that can be easily tuned to overcome the present limitations. Hybrid materials are particularly suited for electronic applications, since their components can be purified to a very high degree [4]. By using specific chemical approaches in order to minimize the influence of the chemical impurities on the electronic performance, the process results can be optimized to be highly reproducible [41] [42]. Silicon-based materials typically play a major role in hybrid composites, therefore there are no clear limits in the potential for integration of Si-based hybrid materials in future device technologies. Aside from this small overview of technological applications of hybrid materials, there is a large variety of other promising applications. My thesis work describes how I fabricated various kinds of hybrid materials starting from a porous material, which was then

impregnated with an organic material, and subsequently investigated the resulting optical and electrochemical properties. In order to do this, it was necessary to deal with critical characterisation issues due to partially destructive aspects of the structural analysis on organic-inorganic hybrids. The results on porous silicon grafted with polyaniline will show how it is possible to increase light absorption of the pristine porous material by the addition of the polymer. Also, a porous structure consisting of a microchannel plate filled with polystyrene and polymethylmethacryilate (PMMA) will be used to investigate signal recovery during time-of-flight secondary ion mass spectrometry (ToF-SIMS) measurements after the damage to the structure that has been induced by using a FIB. These samples will provide a basis for the study of general hybrid composite materials for future applications.

# 2 Materials and methods

## 2.1 Polymers

As mentioned in the introduction, this thesis work is based on the coupling of an inorganic and an organic materials in a hybrid structure. In the case of the inorganic material, this consist of porous silicon or a Si multichannel plate, while the organic part is a polymer. A polymer is a macromolecule composed of a high number of small structural units, of same or different composition, called monomers and kept together by covalent bonding in a process called polymerisation [43]. For example, the commercially important material poly vinyl chloride (PVC) is made from the monomer vinyl chloride. The repeated unit in the polymer usually corresponds to the monomer from which the polymer was made. There are exceptions to this where, before fabricating the polymer, there is need to prepare a new molecule starting from the monomer and then, via a chemical or electrochemical processes, obtain the polymerisation by attaching different chemicals units to the pristine monomer units.

The size of a polymer molecule is defined by its mass and by the number of repeated units in the final molecule. The indicator of the polymer size is called the degree of polymerisation. The vast majority of polymers in commercial use are organic: this means that they are based on covalent compounds of carbon. Other elements may be included in polymer chemistry as hydrogen, fluorine, sulphur and all other elements able to form covalent bonds with carbon. Hydrogen bonding, which arises from an intense dipole associated to hydrogen atoms attached to electronegative elements such as oxygen and nitrogen, is important in the process of formation of protein. Polymerisation mainly refers to substances which form the building blocks for life, such as DNA and proteins, but they have obtained an important role in technological progress in the last decades. Next to natural polymers, there exist classes of synthetic polymers that we use daily, as is the case of polyethylene (PE), polystyrene (PS), PMMA, and poly-tetrafluoroethylene (PTFE). In some cases, by modifying the chemical structure of the monomer it is possible to tune the physical properties of the polymer. Conducting polymers are part of this class of tuneable materials, and they are precious in the fields of microelectronics and microchip development, for example PEDOT:PSS and S-P3MEET:PHOST [44] [45]. These polymers can be perfectly adapted to be used in the aerospace, automotive, and construction industries due to their physical property such high durability, heat resistance, flexibility and resistance to harsh chemical solutions [46–48].

Conducting polymers are identified by the high molecular weight that gives them mechanical properties more valuable than typical industrial materials. Conducting polymers present in some case a higher crystallinity degree: crystallinity means the percentage of material with a crystal structure within the polymer. High crystallinity degree typically means harder material, more resistant and opaquer [49] [50]. In some cases, the crystallinity degree allows polymers to have comparable properties with respect to metal: for instance, as is the case for instance Kevlar, they can have a resistance to traction higher than steel. One of the major applications for conducting polymers is in the batteries field, in particular rechargeable batteries for portable device [51] [52]. Polymers indeed present properties suitable for use in other fields such as electronic circuits, LEDs, diodes and transistors, biosensor, catalyst and gas sensor [53]. Studies on emerging energy sources have also focused attention on polymers for next generation photovoltaics, or multilayer structures of easy fabrication as in perovskite solar cells, since they have lower electrical resistance with respect to metals and semiconductors [54] [55].

In my research, I used different polymers in order to develop different hybrid devices: from commonly used polymers such as PS and PMMA, to a conductive polymer like polyaniline (PANI). Those polymers have been combined with inorganic porous matrices in order to study the interactions between the polymers and the inorganic matrix.

PANI has been electrochemically grafted on porous silicon, and PS and PMMA were inserted with a mechanical process within the channels of microchannel plates. The hybrid structure properties have been studied by optical, electrochemical, photocurrent generation and mass spectrometry characterisation techniques.

### 2.1.1   Polyaniline

Polyaniline or PANI is a conductive polymer discovered by Alan MacDiarmid during experiments on the electrochemical nature of aniline [56]. PANI is synthesised from the aniline monomer via redox reaction using a electrochemical method [57]. It is present in three main different states that are obtained from units coming from reduced ($y$) and oxidized ($1-y$) blocks, depending on the use of acidic or basic environment for the synthesis used for the polymerisation. In Figure 1 it is possible to observe the aniline monomer.
*Figure 1. Part of the structural formula of PANI (source Wikipedia).*

The redox state of the polymer is determined by the value of *y*, which may vary continuously from zero to unity. At *y* = 0, PANI is in its fully oxidized form called pernigraniline with a characteristic blu-violet colour, at *y* = 0.5, PANI is in the form of emeraldine and has a green colour while *y* = 1 corresponds to the fully reduced form called leucoemeraldine, a form with a clear and colourless characteristic [58].

### 2.1.2 Eumelanin

Melanins are a class of natural pigments responsible for the colorations of human skin and hair. Their unique status among natural pigments is due to their socioeconomic and biomedical relevance, encompassing racial pigmentation, skin photoprotection, sun tanning, and pigmentary disorders [59] [60]. Moreover, they display a quite unusual set of physicochemical properties such as broadband mono-tonic absorption in the ultraviolet-visible [61]. These features have suggested the possible use of synthetic (artificial) eumelanins in the development of a new generation of bioinspired electrically active devices. More recently, eumelanin biopolymers have also been proposed for optoelectronic and photovoltaic applications [62]. Eumelanin polymerisation is a complex process that starts from the basic structural formula shown in Figure 2, where the arrow denotes where the polymer continues.
*Figure 2. Part of the structural formula of eumelanin (source Wikipedia).*

Eumelanin will be used in the photoconductive atomic force microscopy (PC-AFM) measurements section, and it was introduced in the porous Si matrix first by insertion of the constituting monomer via spin coating followed then by a polymerisation step in $NH_3$ atmosphere, as described by Pinna et al [63].

### 2.1.3   Poly(styrene)

Poly(styrene) or PS is a polymer derived from the monomer styrene, a derivative of benzene represented in Figure 3.

*Figure 3. Structural formula of the PS (source Sigma Aldrich website).*

The polymer is based on a simple head-to-tail arrangement of monomer units and is amorphous, since the specific position of the benzene rings is variable and hence inhibits crystallisation, making it

easy to form and mould. It finds widespread use in many applications, on account of its desirable properties, combined with its relative cheapness.

### 2.1.4    Poly (methyl methacrylate)

Poly (methyl methacrylate) or PMMA is the most important of the commercial acrylic polymers and it is also known as acrylic glass. It is a transparent thermoplastic often used in sheet form as a lightweight or shatter-resistant alternative to glass.

*Figure 4. Structural formula of the PMMA (source Sigma Aldrich website).*

This polymer is formally derived from poly (acrylic) acid by the replacement of the tertiary hydrogen atom by a methyl group, $CH_3$. In Figure 4 it is represented its monomeric structural formula.

### 2.2    Porous matrices

### 2.2.1    Porous silicon

Porous silicon (PSi) was discovered in 1956 by Uhlir and co-workers [64] while performing electro-polishing experiments on silicon wafers using a solution containing hydrofluoric acid (HF). They found that by applying a current, the silicon surface showed an irregular corrosion where a porous structure, propagating primarily in the <100> direction in the wafer, was formed. In the period between the 1970s and 1990s the interest on PSi increased in spectroscopic studies because of the high surface areas developed [65–67], as a precursor to generate thick oxide layers on silicon[68], and therefore as a dielectric layer in capacitance-based chemical sensors [69].

In the 1990s, Leigh Canham published his results on red-luminescence [70] [71] from porous silicon, describing this phenomenon in terms of quantum confinement of carriers in silicon nano-crystals within the pores walls. After Canham's work, the research interest in porous silicon increased and started to be used in different fields.

Efficient visible light emission made PSi a perfect candidate for silicon-based optoelectronics switches, displays and lasers [71]. During the last twenty years, the optical properties of PSi have become a very intense area of research [72–74]. Aside from its light-emission properties, PSi is also a very promising material due to its mechanical and thermal properties suitable for microelectronics devices [75]. Its large surface area within a small volume, its controllable pore sizes, its convenient surface chemistry and the ability to modulate its refractive index as a function of depth [76] make PSi also a suitable dielectric material for the formation of multilayers [77–79].

The presence of open pores allow the penetration of polymeric and biological substances within the matrix, and it is possible to understand the changes in the filled structure by comparing the optical behaviour changes, induced by the pores infiltration, with respect to the original system. These effects inspired research into different applications fields such as optical sensing applications, drug delivery systems and photovoltaic devices [80] [81].

The electrochemical reaction takes place in an electrochemical cell, as showed in Figure 5.

*Figure 5. Schematic representation of the electrochemical cell used for the preparation of the PSi layer.*

The silicon wafers are cut into 1.5 cm × 1.5 cm samples, that are then inserted in the electrochemical cell where their backside is contacted with a metallic sample holder, while the surface where the

porous layer will be formed is in contact with the etching solution. A second electrode (usually platinum) is then immersed in the electrochemical solution. A voltage is applied between the two electrodes realising a contact trough the HF solution, starting the electrochemical corrosion that leads to the porosification of the crystalline Si. The studies of porous silicon formation started with electrochemical characterisation of its current-voltage *(i-V)* relationships, where the Schottky diode model based on the semiconductor/electrolyte interface played a predominant role [71]. Although additional analysis techniques have been used recently to study porous silicon, the understanding of PSi formation still comes from the *I-V* relationships, and a basic knowledge of silicon electrochemistry is essential to understand the fundamentals of pore formation [82].

The electrochemical process is the same for *n*-type and *p*-type silicon. Under cathodic polarization (negative voltage) the silicon is stable and the only reaction that takes place is the reduction of water at the silicon/HF interface with the subsequent formation of hydrogen in a gaseous state under high cathodic potential. For anodic voltages (positive) the silicon dissolution starts with the pore formation and becomes electropolishing (full dissolution) for higher potentials.

Figure 6 shows the characteristic I-V curve for *n* and *p*-doped silicon. The range of pore formation regimes is indicated. The value that has the physical meaning in this process is the current density (*j*) at the interface between the electrolyte and the silicon interface.

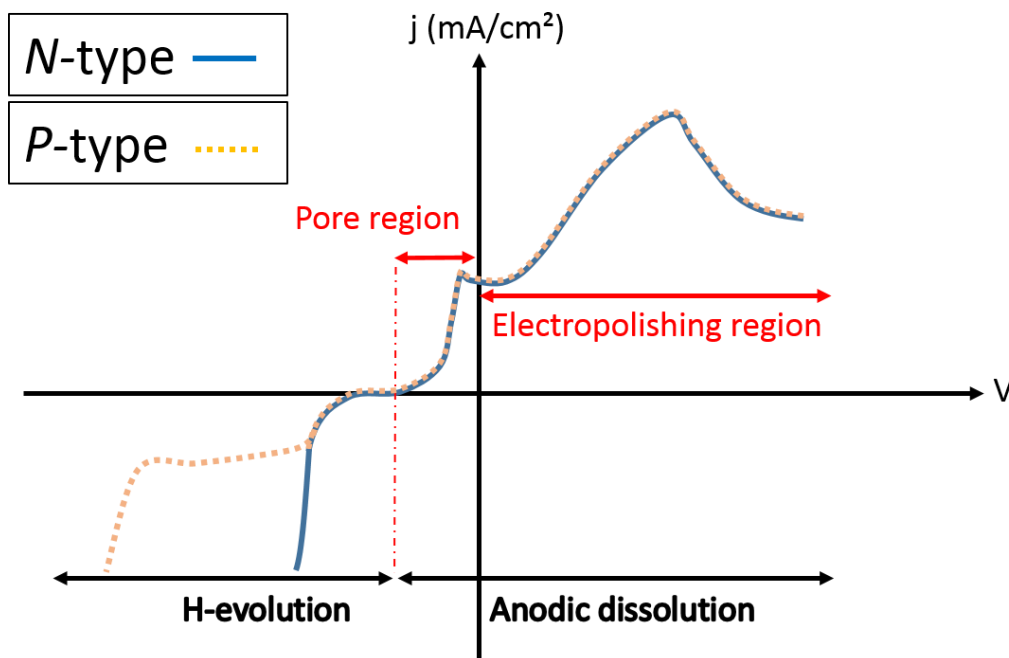

*Figure 6. I-V characteristic for n-type and p-type PSi formation.*

The most accepted chemical reaction that occurs in porous structure formation is described by the following anodic semi-reaction:

$$Si + 6HFH \rightarrow H_2SiF_6 + H_2 + 2H^+ + 2e^-$$

The silicon product after this reaction is $H_2SiF_6$. A further dissolution happens when more holes are available at the pore tips, giving a directionality in the pore formation in the depth. This direction is given by the anodic current path in the silicon. After the pore formation regime, a further increase in the formation current leads to the electropolishing regime, where silicon is fully dissolved.

In Figure 7, we can see an example of PSi prepared in the PoroSiLab at the University of Cagliari for these thesis experiments: a mesoporous silicon matrix formed from heavily *n*-doped Si wafers.

*Figure 7. SEM image of a PSi cross section obtain by etching in HF 15% with a current of 25mA.*

It is possible conclude that the PSi formation process (and the corresponding current and voltage curves) depends on:

- *The HF concentration*: higher concentrations lead to smaller pore size;

- *The solvent in which the HF is diluted*: the use of ethanol as a surfactant gives higher homogeneity, considering that the porous silicon is hydrophobic but at the same time organophilic;

- *The type and level of silicon wafer doping*. For example, the use of low *n*-type doping levels require illumination to supply hole carriers, and the average pore size depends on the type and level of doping;

- *The etching time*: in the normal pore formation regime, the porous layer thickness is directly proportional to the formation time.

## 2.2.2 Microchannel plate

Organic-inorganic test devices used in chapter 4 were made using a Long-Life™ MCP-10 microchannel plate (MCP) (Photonis, US), commonly used in ToF detection systems [83]. The MCP (see Figure 8) consists of a regular array of hexagonal close packed open tubes with 10 μm hole diameter and a centre-to-centre separation of 12 μm. These holes are tilted at 12° to the surface normal. The MCP is made from glass tubes sintered together with a rubidium-containing Nichrome coating for secondary electron emission. The holes are subsequently filled with either PS or PMMA using a 4-step procedure summarized in Figure 8 and described by Steinhart et al [84].

The tubes are filled by melting the polymers and pressing them into the tubes in a vacuum oven. This regular structure of organic and inorganic phases is suitable for evaluating the lateral resolution, the organic material damage effects and the data validity during measurement.

As reported in Figure 8 (top line), first, the MCP was degreased in a bath of 20% nitric acid (Sigma-Aldrich, UK) for more than 24 hours and subsequently rinsed with purified water and acetone (Sigma-Aldrich, UK). The dried MCP (bottom line from right side) was placed in a glass Petri dish and the surface of the MCP was covered with powdered polystyrene (molecular weight 2430, Sigma Aldrich, UK) or PMMA (molecular weight 340000, Sigma Aldrich, UK). A metal weight of 500 g was placed on the polystyrene. Keeping this arrangement, the polymer was annealed to 200 °C for 5 h in a vacuum oven allowing the polymer to melt and fill the channels in the MCP. In Figure 8, on the bottom line, at the left hand end is an optical image of the filled MCP after the filling procedure.
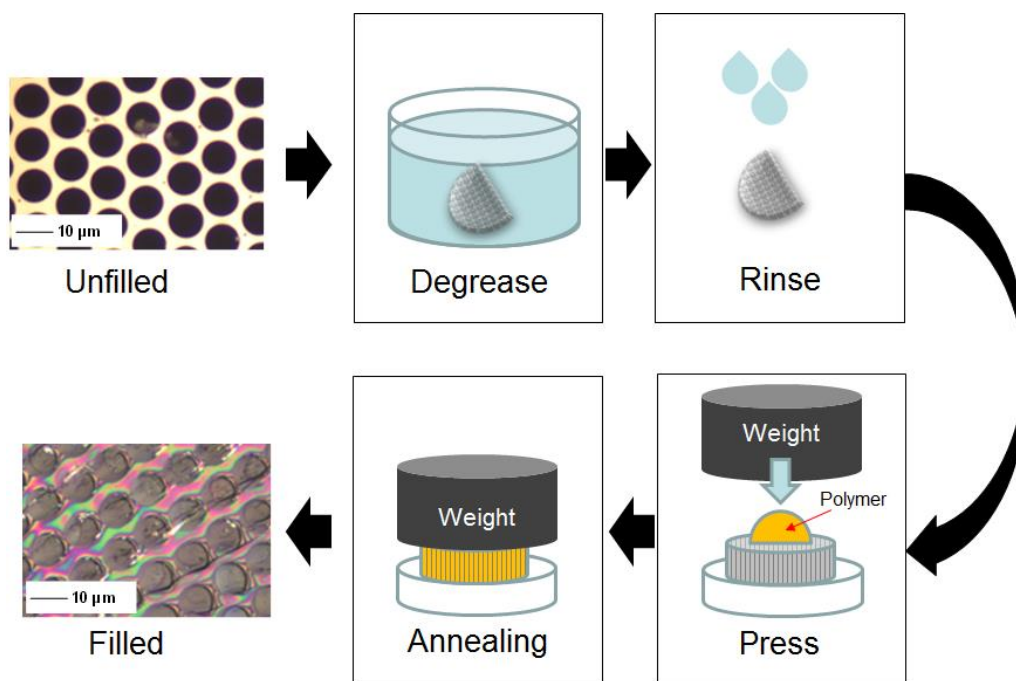

*Figure 8. Schematic representation of the 4-steps filling procedure of the MCP.*

## 2.3   Electrochemical techniques

### 2.3.1   Cyclic voltammetry

Electrochemistry is a powerful technique to test reactions that involve electron transfer, electron flow and chemical changes in a substrate. In this work, it has been used for the grafting of the PANI to the PSi. The advantage of electrochemistry resides in the simplicity with which thermodynamic and kinetic parameters can be measured. The PSi grafting process described in section 3.2 involves different electrochemical techniques such as cyclic voltammetry and potentiostatic measurements [85] [86]. Cyclic voltammetry is a technique widely used to investigate the Redox process of molecular species and electron transfer-initiated chemical reactions as catalysis. CV data are usually reported by using the IUPAC convention as shown in Figure 9.
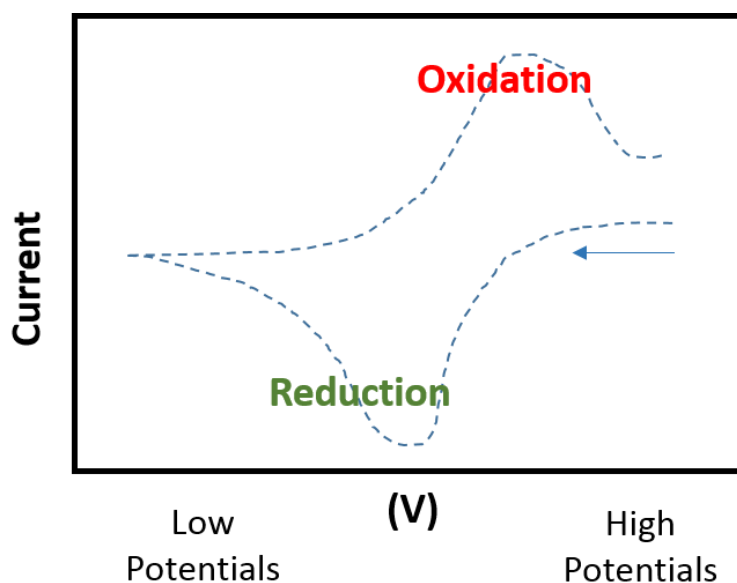

*Figure 9. Schematic representation of a cyclic voltammogram. The arrow indicates the process direction..*

The dashed line on the Figure 9 is a typical voltammogram or cyclic voltammogram, where the *x* axis is the applied potential (E), and the y axis is the response in term of the resulting current (I) or current density (J) passing through the system: for negative current values or densities it is possible to register oxidation reactions, while for positive values of current it is possible to observe peaks related to chemical reduction processes. The arrow indicates the sweep direction for the potential range. An important parameter that has to be taken into account is the scan rate, which is the constant variation rate of the applied potential during the experiment.

### 2.3.2   Electrochemical impedance spectroscopy

In this section we will describe the behaviour observed during the early stages of grafting by using electrochemical impedance spectroscopy (EIS). One of the relevant properties of porous samples, including PSi, is a large developed area that is complex to characterise in detail. By using EIS, it is possible to obtain information on the inner pores surface and on its modifications, by recording the system response (the phase variation) to a solicitation given by applying a current intensity (galvanostatic regime) or voltage (potentiostatic regime) oscillating at frequencies distributed in a several orders of magnitude wide range [87].

For our EIS measurements, we chose the galvanostatic regime (Galvanostatic EIS, GEIS), consisting in the perturbation of the system through sinusoidal currents of small amplitude (mostly from 5 to 10 mA) overlapped to a continuous current to observe the response of the system to the perturbation [85].

The data interpretation, generally made by using a model circuit whose behaviour reproduces the experimental one, gives indication on the modifications incurring at the interfaces between different phases. Those interfaces may exist directly inside the semiconductor itself (as for instance when derived from different morphologies, or between different distinctive crystalline phases), or between the solid phase and the medium where the semiconductor is placed, as is the case with an electrolytic solution.

The samples response is generally due to the rearrangement of the electrical charge, following the oscillating perturbation, in the various interphases. The data interpretation is performed by using equivalent electrical circuits, that is an electronic circuit with a certain number of circuital elements combined in series and/or in parallel and exposed to the same alternate signal is used to stimulate the experimental system. The data fitting with equivalent circuit gives, under the simulated experimental conditions, a signal response that is overlapped to the experimental response measured from the real system. The correct data interpretation comes from circuits whose elements are correctly representing the samples parts that are responding to the electrical stimulations (interfaces, ions moving within an electrochemical solution, …). In fact, in an electrochemical cell, the kinetics at the electrodes, the chemical reactions and the diffusion processes can affect the electron flux and can be therefore modelled by resistors, condensers and inductors. In conclusion, with EIS analysis, based on the knowledge of the physical and chemical phenomena that rules the examined process, it is possible give a physical meaning to the electrical equivalent circuit and to the chosen circuital parameters.

If the use of a given equivalent circuit leads to a good fit of the experimental data, it can be considered consistent and accurate. It is also important consider that it does not exist one only one equivalent circuit able to describe the behaviour of the system. For this reason, the best choice of the equivalent circuit is the one that gives the best fit while having the most consistent real physical description of the system.

In Figure 10, Figure 11 and Figure 12 are shown an example of the representation of EIS impedance results by using the three standard graph types:

- *Nyquist plot*: shows the relation between the real (|Z Re| or Z') and the imaginary part (|Z im| or Z'') of the impedance (Figure 10).
- *Bode plot*: real part of the impedance *vs.* frequency (Figure 11);
- *Bode2 plot*: the phase ($\vartheta$) in radians or degrees *vs.* frequency (Figure 12).

*Figure 10. Nyquist curve of PSi*

*Figure 11. Bode-impedence curve of PSi.*

*Figure 12. Bode-phase curve for PSi.*

The phase is directly related to the impedance by the relation expressed in the formula:

$$\theta = \arctan(\frac{-|Z\ im|}{|Z\ Re|})$$

In our case, the circuital choice and the curve simulations have been performed by using the EISSA software (Electrochemical Impedance Spectroscopy Spectrum Analyser, http://www.abc.chemistry.bsu.by/vi/analyser/).

## 2.4 Photocurrent measurements

### 2.4.1 Spectral dependence using low-pass filters

To study the behaviour of the PSi sample grafted with PANI, the photoconductive characterisation has been carried out by first depositing sputtered semi-transparent gold contacts on the samples surfaces and then using low-pass filters to characterize the spectral behaviour of the samples. To investigate the local photoconductive behaviour of the samples, PC-AFM measurements were also performed.

Optical low-pass filters, also known as anti-aliasing or "blur" filter, were designed by camera manufacturers to eliminate the problem of patterns that occur when a scene or an object that is being photographed contains repetitive details (such as lines, dots, etc.) that exceed the sensor resolution, by blurring what actually reaches the sensor. Optical filters can be considered as devices that transmit light selecting a cutoff wavelength/frequency. They are usually implemented as glass or plastic sheets in the optical path. Low-pass filters (Figure 13) transmit only the light having energy below the cut-off energy and absorb or reflect the rest.

*Figure 13. Optical filter used in the photocurrent generation experiments.*

### 2.4.2 Photoconductive atomic force microscope (PC-AFM)

The standard method used to analyse the photocurrent generated from of PSi and PSi/polymer gives a response originated from a wide porous surface, because the illumination of the sample is over a large circular area. However, it is important, for an optimization of the samples behaviour, to understand how the photocurrent generation behaves locally, at the pores diameter length scale. Therefore, a suitable method is needed to identify the pores and register the current under illumination in a single pore. These information can be obtained by using a PC-AFM.

The PC-AFM is a type of scanning probe microscopy (SPM) analysis method developed for property analysis of photovoltaic elements. With a technique based on the principles of a standard AFM equipped with a conductive tip, PC-AFM employs an additional attached light source to shine light onto the photosensitive element. Normally, the light source is located beneath the specimen, and light is shone onto the specimen through a transparent conductive oxide layer (e.g. Indium tin oxide). In our case the sample is not transparent to the light, so we modified the system in order to have the light source focused on the top of the sample, as shown in Figure 14.

*Figure 14. Schematic representation of the PC-AFM configuration.*

Through the use of PC-AFM, the conversion efficiency of the sample can be analysed at the nanoscal level, and visual analysis of phase separation, charge generation, and charge transport can be performed [88]. The light source is a green laser with wavelength $\lambda = 532$ nm, chosen to give the maximum response from the polymer. This method is especially useful in studying the relationship between morphology, material composition, and light wavelength that impacts the photocurrent generation of the specimen [89].

## 2.5 Secondary ion mass spectrometry (SIMS)

The growing interest in hybrid organic-inorganic devices and materials generates a need for methods suitable for their characterization. High-resolution chemical imaging using SIMS in combination with a FIB milling is a promising method to investigate buried interfaces in hybrid materials. However, there is a lack of guidance for analysts on how to achieve reliable and reproducible FIB-SIMS measurements.

SIMS is a mass spectrometry technique that detects ionized particles emitted from a solid surface bombarded by energetic primary particles, such as electrons and ions. Based on mass spectrometry principles, SIMS is used to investigate the molecular, elemental and isotopic composition localized in the microscopic scale in solid samples and thin films. A primary ion beam, impacting on the surface of the region of interest, generates a cascade of secondary ions that are then analysed by a mass spectrometer. Primary particles can be atomic species, for example $Bi^+$, $Ga^+$, $Cs^+$ or small clusters and polyatomic ion species such as $Ar_n^+$, $Bi_3^+$, $C_{60}^+$, while secondary charged particles can be electrons, molecules, polymer fragments or neutral atom species.

The first example of SIMS measurements, made possible by the use of ultra-high vacuum pump technology, was in the 1949 by Herzog and Viehböck [90], at the University of Vienna, Austria. Later, in early 70s, two different projects in USA and France brought the development of the first instruments based on a magnetic double focusing sector field mass spectrometers and the possibility to use Argon as primary ion beam. By 1975, K. Wittmaackand and C. Magee developed a quadrupole mass analyzer for the SIMS [91] [92]. At the same time, A. Benninghoven introduced the still commonly used method of static SIMS, which allows surface analysis to be performed by using a primary ion current density small enough that only a negligible fraction (typically 1%) of the first surface layer contributes to the measurement [93]. The first commercial SIMS system was developed by the company CAMECA S.A.S and had an immediate impact on materials science and surface science. Instruments of this type use pulsed primary ion sources and time-of-flight mass spectrometers and were developed by Benninghoven, Niehuis and Steffens at the University of Münster, Germany and by Charles Evans & Associates. The instruments that we used in this work have been developed and built by IONTOF Gmbh, Germany.

In SIMS, a primary ion beam impinges on the surface of a sample The secondary ions generation process that follows the impact of the primary ions beam involves a dynamic part, where monoatomic and polyatomic clusters are desorbed from the surface of the sample, and an ionization process, in which a fraction of the sputtered particles become positively or negatively charged (see schematic representation in Figure 15).
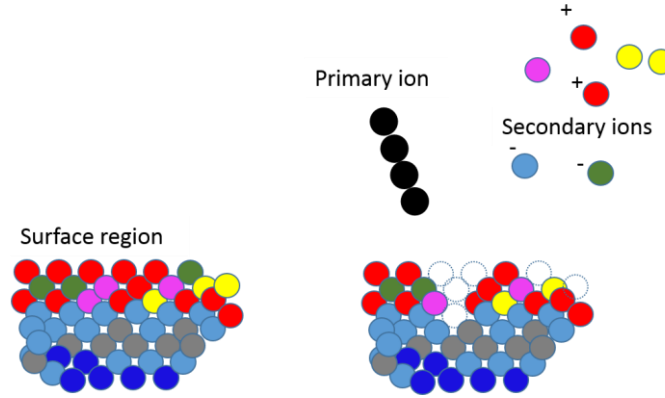

*Figure 15. Schematic of secondary species emission.*

The secondary ions are collected, filtered and focused by the secondary ions column, composed by a system of lenses and deflectors for energy and mass filtering. Secondary ions generation is a complex mechanism that includes the sputtering and the ionization that both finally result in the emission of the secondary ions species being measured. For any sputtered surface, the species measurement depends on the secondary ion yield, that is by the number of ions produced by sputtered ions or molecule (analyte for simplicity) and is strongly influenced by the electronic states that affect the quantitative analysis. The basic equation that describes SIMS process is:

$$I_s^m = I_p y_m \alpha^{\pm} \theta_m \eta$$

Where $I_s^m$ is the primary ions current relative to the species $m$, $y_m$ is the sputter yield defined as the number of secondary analyte particles sputtered by one primary ion particle, $\alpha^{\pm}$ is the ionization probability for the sputtered positive or negatives analytes, $\theta_m$ is the fractional concentration of $m$ on the surface of the sample that is being analysed and $\eta$ is the ion transmission efficiency of the instrument, from the specimen, through the various lenses, mass analyser and apertures, up to the detector. The product $\alpha^{\pm}\eta$ is referred to as $s$, the useful yield, that is the number of analyte particles detected per analyte particle sputtered.

Sputtering of singular species has been predicted by the Sigmund sputter theory, based on the model of impact cascade and the interaction potential between the atoms in the target material [94]. With this theory, it is possible to quantitatively predict sputter yields and their dependence on primary ions properties such as energy, angle of incidence, and mass.

SIMS mainly has two operation modes that depend on the primary ion dose that is acceptable during the analysis: static and dynamic SIMS. For static SIMS, the data collected are obtained from less than 1% of the outermost monolayer of the sample under examination and the acceptable limit for the primary ion dose is $<10^{13}$. By contrast, in dynamic SIMS the data is collected from many atomic layers situated at and below the outermost sample surface and the minimum dose is around $10^{17}$ ions/cm².

## 2.5.1 Primary beam: LMIG

A liquid metal ion gun (LMIG) is used to provide primary ion beam for the ToF-SIMS system used in this work. The best-known sources are bismuth and gallium. LMIGs can provide an atomic beam or a cluster beam. The choice of the beam depends on the nature of the material to be analysed. A schematic drawing of the LMIG is shown in Figure 16.

The LMIG is essentially constituted by 3 parts:

- Support leg that also works as an electrical contact;
- Emitter constituted by a needle and a reservoir coated with the metal used for generation of ions;
- Extractor for the extraction of the metal ions and cluster ions.

The liquid metal reservoir is in contact with and wets a sharp tungsten tip, while a high excitation field pulls out ions to a cone with a radius on the range of tens of nm. Ions are emitted by field ionization and accelerated down the ion column. The extractor works with a potential range typically between -5 and -10 keV with respect to the source. An intense electric field around the tip generates an electrostatic force that allows the movement of positive ions forward while electrons move backwards to the needle. The principal ion sources used are $Ga^+$ and $Bi_n^+$ because they tend to introduce minimal chemical effects into the substrate under study and hence have a minimal effect on the secondary ions yields.

Other ions can be produced by heating the source to the melting point of the alloy as happens for the Manganese and the Bismuth produced from the BiMn alloy and then selecting the required ion cluster or metal through careful control of the pulse timings, which will be different depending on the mass of the ions required.

*Figure 16. Schematic representation of the LMIG.*

### 2.5.2   Focused Ion Beam: FIB

The Focused Ion Beam (FIB) uses a beam of positively charged ions of high atomic mass (commonly $Ga^+$) following the same principle of emission and interface interaction explained for the LMIG in section 2.5.1 . Although a FIB may be used as a primary ion beam in SIMS, FIB here refers to an ion beam which is primarily used to mill samples for subsequent analysis. This use of FIBs is common in electron microscopy.

A common choice of ion source is the liquid-metal $Ga^+$ ion source, because Ga has a low melting temperature, low volatility, easily distinguishable ions in post imaging and the weight is adequate to mill both organic and inorganic materials and, above all, to mill heavier elements. The liquid $Ga^+$ source works as shown in Figure 16.

The FIB operates by raster scanning the focused beam across the surface of the sample with a determined pixel size and dwell time. The crater size can be determined from the beginning by the acquisition of a secondary electron image of the area to analyse.

The most important parameter of the FIB is the accuracy of the ion milling and the focus. The accuracy of the ion mill is important to control, as inconsistencies in the ion mill degrades the cutting/shaping. If the process is repeated by imposing different numbers of scans, the deterioration often propagates through the protocol.

The ion beam has a current profile with a focused core and a Gaussian current density distribution, whose long tails decrease with distance. This beam profile limits the accuracy of the mill, that can still achieve submicron cutting with enough precision without the use of any particular lenses [95].

### 2.5.3   Depth profiling and gas cluster

Depth profiling provides SIMS with the ability to examine the substrates of interest at different depths within a sample. The depth profiling goal is to assess the result of process steps such as ion implantation, thermal annealing, epitaxial growth and multilayer material distribution in general, buried interfaces, and contaminants. Essentially, a depth profile is a plot of the two signals recorded by the instruments: the intensity of the ion signals (or concentrations) and the sputtering time (or in case of known sputter rates or yields, the depth). The important characteristic needed to perform the depth profile is given by the depth resolution. This is the measure of the ability to localize a certain concentration at a certain depth, distinguishing between adjacent features at different depths. It is mostly defined as the depth over which a signal from a given layer suddenly rises from 16% of its

maximum intensity to 84%. The same is valid in the opposite case in case of signal decaying. One of the most used method to perform depth profiling is the so-called dual beam mode (Figure 17).

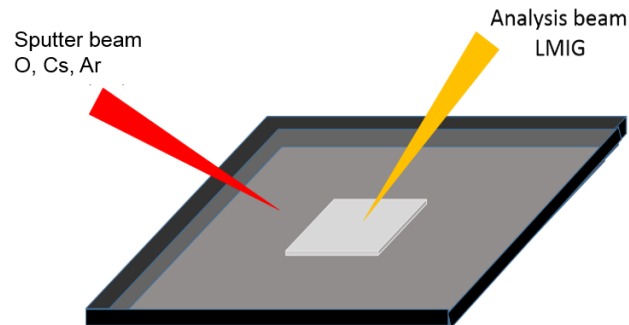

*Figure 17. Dual beam ToF-SIMS schematic configuration*

This configuration represents a major development in ToF-SIMS, and has been developed by the Benningoven group in the University of Münster [96]. In dual beam SIMS, a sputtering beam with a high flux density and long pulse length, about 80-90 μs, is interlaced with a sampling beam (usually the primary ion beam coming from an LMIG, which is tightly focused) with a dose in the range of the static SIMS and a short pulse length of about 1-50 ns. The ToF extraction is performed in a time range of 5-10 μs, that is between the analysis gun pulse and the sputter gun pulse. The most important parameters for high performance depth profiling derive from the ability to reject the sputtered material from the walls of the carter and from the sample surface, determining in this way the dynamic range and the profile shape in the low dose regime. The sputtering beam is usually oxygen, caesium or argon. In this thesis work, we used as a sputter beam an Argon Gas Cluster Ion Beam (GCIB) obtained by injecting and condensing the single gas atoms into neutral atom clusters [97]. The gas is then inserted inside a nozzle with a pressure gradient. The difference in pressure facilitates the cluster formation. In Figure 18 a schematic representation of the gas travel and focusing is shown.
*Figure 18. GCIB gas cluster formation procedure.*

The atoms and cluster have no charge and they keep their velocity and direction outside the nozzle chamber. The cluster is then ionized, extracted, accelerated and focused in order to produce a beam apt to impact on the sample surface with an energy in the 2-40 keV range.

### 2.5.4    Mass filters

To analyse, collect, filter and focus the secondary species emitted from the sample surface there is a dedicated secondary ion column. The mass filters used within the secondary ion column define the capability of the SIMS instrument used. The most important mass filters in commercial use are:

- the quadrupole mass filter
- the magnetic sector mass filter
- The time-of-flight mass filter.

The first filter (quadrupole mass filter) takes its name from the use of combination of a DC and a radio frequency electric (RF) fields applied to 4 parallel rods. In this way, it is possible separate the ions based on their mass-to-charge ratio. The quadrupole mass analyser is tuned to obtain the transmission of secondary ions while providing constant resolution m/Δm through the mass range, with the advantage of being able to switch to different masses at a much faster rate than magnetic sector mass filters, but the transmission usually falls with increasing mass order as $\sim m^{-1}$.

The magnetic sector mass filter was the first filter used in conventional mass spectrometry and it is based on the measure of the curvature radius of the path taken by an ion that passes through a magnetic field. Ions are extracted and accelerated by a potential of ~5 keV. Traversing a magnetic field, a charged particle experiences a force field orthogonal to the magnetic flux lines and its original

trajectory then adopts a circular path. This is indicated in the Lorentz force law and described by the equation:

$$R = \frac{1}{B}\left(\frac{2mV}{z}\right)^{\frac{1}{2}}$$

where R is the radius of curvature for an ion with mass to charge m/z, B is the magnetic field and V is the acceleration potential. By using this type of filter, it is possible to generate a secondary ion image that can be shown in real time on a fluorescent screen or with computer software via a position-sensitive detector. The major disadvantages associated with this kind of filter are mostly due to the large size of the instruments, the degradation in the detection limits when implementing high-mass resolution above some limits and the relatively limited accessible mass range in commercially available SIMS instruments.

The last one in the list, the time-of-flight filter, is the one used in this thesis work. Conceptually, it is the easiest to install in a mass spectrometer. With this filter, the secondary species are accelerated to a given potential between 2 and 8 keV. The higher the mass-to-charge-ratio (m/z) of the particles and ions, the lower will be the travel velocity along the path. The time the ions take, for a select applied voltage V, to travel across the flight tube path length (L) is given by the equation:

$$t = L\left(\frac{m}{2zV}\right)^{\frac{1}{2}}$$

ToF-based instruments are able to perform the quasi-simultaneous collection of all secondary ions. Following the analysis via computer software it is possible to select and analyse specific ions. The fact that all the data are saved over a wide m/z range is a really unique advantage in cases where the signal of interest is not detected during the measurements, as is the case for the quadrupole and the magnetic sector detectors, where the signals of interest need to be specified from the beginning. Some issues do affect this kind of filter, as the impossibility, in case of contamination, to bake the instrument without modifying the magnetic properties in the analyser, the large data files produced per analysis, or the dependence of the mass resolution and the m/z ration on the surface quality (ToF is primarily useful just in case of smooth surfaces however delayed extraction processes are able to help with this).

### 2.5.5 Instrumentation

In this study, a TOF-SIMS 5 (ION-TOF GmbH, Germany) system was used. This consists of a ToF analyser normal to the sample surface, a dual $Ga^+$ FIB and $Ar^+$ GCIB sputter profiling ion source mounted at 45° to the sample surface and a BiMn LMIG. The dual source ion column provides a 20 keV $Ar^+$ GCIB or a 30 keV $Ga^+$ FIB ion beam aligned in the same direction. The dwell time used for the FIB was 25 ms/pixel and sample cross sections were generated using 1, 2 and 3 passes of the milling. SIMS analysis is made using a 30 keV $Bi_3^+$ ion beam, also at 45° to the sample surface but in an azimuth at 90° to the $Ga^+$ and $Ar^+$ GCIB beam. Low energy electrons are used for charge neutralization and are provided by a flood gun delivering a current of 5 μA with an energy of 20 eV, mounted at an angle of 57° to the sample normal. The secondary ion and electron imaging of the cross section are made using a mass separated 30 keV $Bi_3^{2+}$ DC beam in the high lateral resolution, "Fast Imaging", mode operating with the analyser in delayed extraction mode.

# 3  Mesoporous hybrid material experimental results

In this chapter I will present the work published in the papers:

- Tiddia, M.; Mula, G.; Sechi, E.; Vacca, A.; Cara, E.; De Leo, N.; Fretto, M.; Boarino, L. 4-Nitrobenzene Grafted in Porous Silicon: Application to Optical Lithography. *Nanoscale Res. Lett.* **2016**, *11* (1), 436.

- Tiddia, M.; Mula, G.; Mascia, M.; Sechi, E.; Vacca, A. Porous Silicon–polyaniline Hybrid Composites Synthesized through Electroreduction of an Aryldiazonium Salt: Preparation and Photocurrent Properties. *RSC Adv.* **2016**, *6* (104), 101880–101887.

## 3.1   Introduction

In this section of the thesis, the work on the hybrid structure obtained from porous silicon and polymers is presented, and the results of an experimental study focusing on the electrochemical and photocurrent properties of porous silicon (PSi) coated with polyaniline (PANI) is described. The fabrication of a stable and uniform coating is obtained by a 3-steps approach. In the first step, PSi electrodes were functionalized by electrochemical reduction of 4-nitrobenzenediazonium (NBD) salts in an acetonitrile media. In the second step, the nitro groups were electrochemically reduced to amino groups. In the last step, aniline polymerisation was performed on the surface of the aminophenyl-modified PSi. The effect of the grafting on porous silicon has been compared by analysing samples prepared by direct polymerisation of aniline on the PSi surface skipping the first 2 steps.

By stopping the process at the first step of grafting, we observe that the porous silicon resistance to alkaline solution attacks is improved by the pore functionalization with the electrochemical reduction of 4-nitrobenzendiazonium salt. This method provides porous silicon with strong resistance to the etching solutions used in optical lithography and allows the fabrication of tailored metallic contacts on its surface [86]. The samples maintained open pores after the grafting, making them suitable for further treatments (as the PANI electrochemical deposition). This is clearly a mandatory property to allow for the remaining two further steps of polymerisation to be feasible. Optical lithography was performed on the functionalized samples, and electrochemical characterisation results will be shown.

The samples were characterised by reflectivity and photocurrent measurements. With the sample 3-steps process, we will also show the modified absorption spectrum of the NBD-modified hybrid structures is greater than those of the pristine PSi. Depending on the wavelength, it is possible to record an increase of the photocurrent generation capability, which shows increases in the range of

41

the 20% to the 30%, and also extends to wavelengths where pristine PSi does not absorb and does not show any photo-generation behaviour. The entire process can be explained by the formation of a *p-n* junction between the porous silicon and the polymer.

In the last decade, there have been many attempts to fabricate hybrid organic/inorganic structures to obtain materials with optimal electrical and optoelectronic properties for several kinds of devices, such as light-emitting devices, solar cells, sensors and biosensors [98]. To this end, conducting polymers (CPs) have attracted significant interest and remarkable effort has been put into the understanding their conduction mechanisms and properties [99–101]. A large varieties of CPs, with different structures and compositions have been proposed, such as polyacetylene (PA), polyaniline(PANI), polythiophene (PT) and polypyrrole (PPy) [102]. CPs show good conductivities, although lower than metals, maintaining the mechanical properties of a polymer. Moreover, CPs can switch their conductivity from p-type (electron-acceptor) to n-type (electron-donor) and vice versa [103]. In particular, PANI possesses outstanding properties such as a wide range of conductivity (from insulating to metallic regime), unique redox tunability, good environmental stability, low cost and ease of synthesis, as well as electrical conductivity significantly higher than that of a standard polymer [104]. Researchers have explored the applications of PANI in solar cells, capacitors and supercapacitors, as well as ion and gas sensors [105–109].

Among the methods to synthesize PANI, different electrochemical techniques such as cyclic voltammetry [110], potentiostatic [111] [112] and galvanostatic measurements [113] [114] have been successfully adopted. Depending on its redox state, PANI can be obtained in different forms: leucoemeraldine (LE), emeraldine (E) and pernigraniline (PNA). The only conducting form of polyaniline is emeraldine salt, obtained by doping or protonation of emeraldine base with the imine nitrogens protonated by acids [115]. The electrochemical growth and redox mechanisms of PANI have been widely investigated [116] [117]. The process starts with the formation of dimeric species from nucleophilic attack of the aniline on the nitrene cation radical, resulting in three dimerization products, as well as competitive degradation reactions [118]. To realize hybrid nanocomposite materials a porous matrix can be coupled with this highly conductive organic conjugated polymer [119] [120].

## 3.2   NBD grafting procedure and EIS analysis

PSi was prepared by using highly phosphorous-doped Si wafers (Siltronix) using a $HF:H_2O:EtOH$ solution with a 15:15:70 proportion, respectively, and a current density of −50 mA/cm$^2$ [121]. The electrochemical experiments were performed at room temperature using an AUTOLAB PGSTAT302N

(Metrohm, Switzerland) potentiostat/galvanostat equipped by a frequency response analyser. The electrodeposition of 4-NBD on PSi surface has been obtained using an can solution containing 2 mM 4-NBD and 0.1 M (TBAPF6) as supporting electrolyte. The current density was calculated with respect to the external surface of the samples. As shown in **Figure 19**, an irreversible diazonium reduction peak is present in the first cathodic scan at −0.7 V, indicating the cleavage of dinitrogen and the subsequent one-electron covalent reaction between the silicon and nitrobenzene radicals. As the number of cycles increases (see **Figure 19** and **Figure 20**), the reduction peak becomes less evident and a shift towards negative potentials is observed.

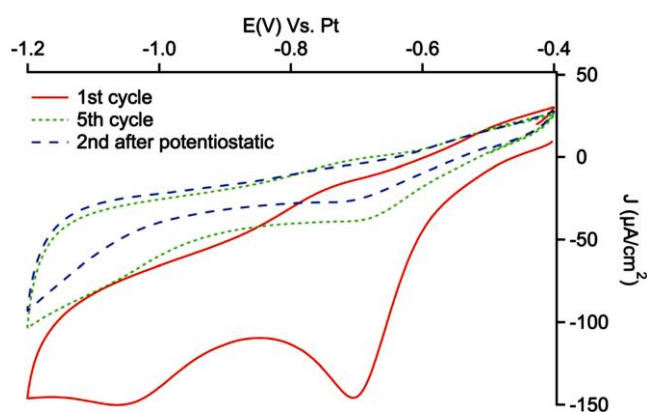

*Figure 19. Cyclic voltammetries of PSi electrode in 2 mM NBD + 0.1 M (TBAPF6) at 10 mV s^-1.*

*Figure 20. Example of current density vs potential for five cyclic voltammograms used for grafting process.*

As previously reported in the literature [115] [120] [122], the modification of monocrystalline H-terminated silicon can be recognized by a well-defined reduction peak during the first voltammetric cycle, indicating a fast and easy reduction of aryl diazonium cations to aryl radicals that can be grafted on the surface (aryl will be indicated with Ar). In the second scan, the peak disappears nearly completely, and this is indicative of the blocking effect of a dense monolayer which hinders further reduction at the surface. In our case, given the large developed surface of PSi, the diazonium reduction peak is still

visible after five cycles, indicating that the density of grafted molecules is not high enough in the first cycle. In fact, the porous structure of silicon offers a very large surface and during subsequent cycles, further electron transfer is possible. The negative shift of the reduction peak can be attributed to exchange of electrons between the silicon and diazonium molecules that are reduced on the already grafted molecules allowing the formation of a multilayer structure. Figure 21 shows the time evolution of the potentiostatic current during the 4-NBD deposition. The applied constant voltage was −1.1 V. As can be seen, current intensity is reduced by about one order of magnitude after about 2 min, indicating a complete passivation of the surface.

*Figure 21. Current density vs time for potentiostatic method used for grafting process.*

In order to gain information about the nitrophenyl layer, whose thickness can be estimated as 1–2 nm from the reduction of the average pore opening diameter in the case of 12 CV cycles samples, EIS measurements have been performed at OCP in a 4-NBD-free solution. Figure 22 shows the Nyquist and Bode plots for PSi modified using five voltammetric cycles (Figure 22 (b), (d), (f) ) and potentiostatic mode (Figure 22 (a), (c), (e)): in both cases, the deposition of the organic layer produces a significant increase of the impedance (blue curves) with respect to unmodified pristine PSi (purple curves).
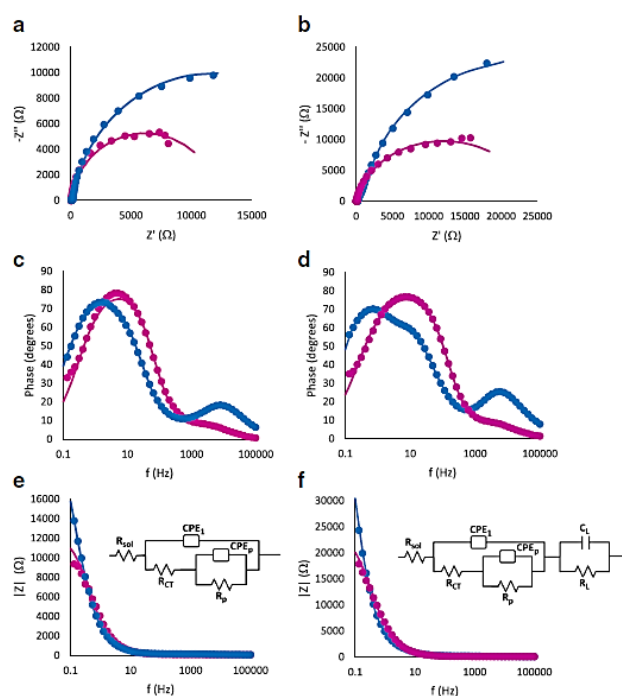

*Figure 22. Nyquist and bode plots for pristine PSi in purple vs grafted PSi in blue (**a c** and **e** in case of potentiostatic approach and **b d f** in case of CV)*

As shown in the Bode phase plots in Figure 22, the modification of the silicon surface allows the increase of the phase angle at high frequencies for both deposition techniques, being higher for the sample grafted with five CV cycles. The second phase maximum present in pristine PSi is shifted towards lower frequencies after the grafting process: moreover, the sample modified by cyclic voltammetries shows a new overlapped wave indicating the characteristic parameters of the electrodes. The impedance spectra of unmodified PSi have been modelled with the equivalent circuit proposed for porous silicon electrodes (see inset in Figure 22 (e)).The following elements have been inserted in the circuit: the solution resistance (RS), a parallel combination of the charge transfer resistance (RCT) and a constant phase element (CPE) instead of double layer capacitance (Cdl) for considering roughness effects and variation in the composition of the surface. The CPE exponent, n, is generally associated with surface imperfections [123]. The second parallel combination (Rp and Cp) has been introduced to account for the resistance and capacitance of the porous layer. The impedance spectra obtained for PSi modified by the potentiostatic mode have been modelled with the same equivalent circuit, but using a CPE for the porous layer while for the sample modified with five CV cycles, a third parallel combination has been added (see inset in Figure 22 (f)). RL and CL elements can be related to the presence of an organic layer with high degree of coverage of the overall surface. A good fit of the impedance spectra ($\chi 2 < 8 \times 10^{-4}$) has been obtained with these equivalent circuits. The fitting parameters are presented in Table 1. RCT increases after the grafting process, while the capacitance of the CPE element decreases indicating an increase in the thickness of the electronic

double layer. Both the effects can be related to the presence of the phenyl layer on the surface. The exponent of the constant phase element associated with the pores (np) is indicative of the presence of inhomogeneity or variation in the composition of the surface inside the pore. For the sample modified by potentiostatic mode, np approaches to 1, which can be related to a poor modification inside the pore structure, while for the sample modified by five CV cycles, we obtain np << 1. Indication of higher degree of coverage in the surface inside and outside the porous structure is given by the RC parallel combination required to model the sample modified by five CV cycles.

The cyclic voltammetries related to the second electrochemical step of nitro group reduction to amine are presented in Figure 23: a wide reduction peak is present in the first potential scan, while in the reverse scan an anodic shoulder can be appreciated between -0.7 V and -0.6 V. Well-shaped redox peaks are visible when the reduction is performed at 10 mV/s of scan rate (see inset of Figure 23).

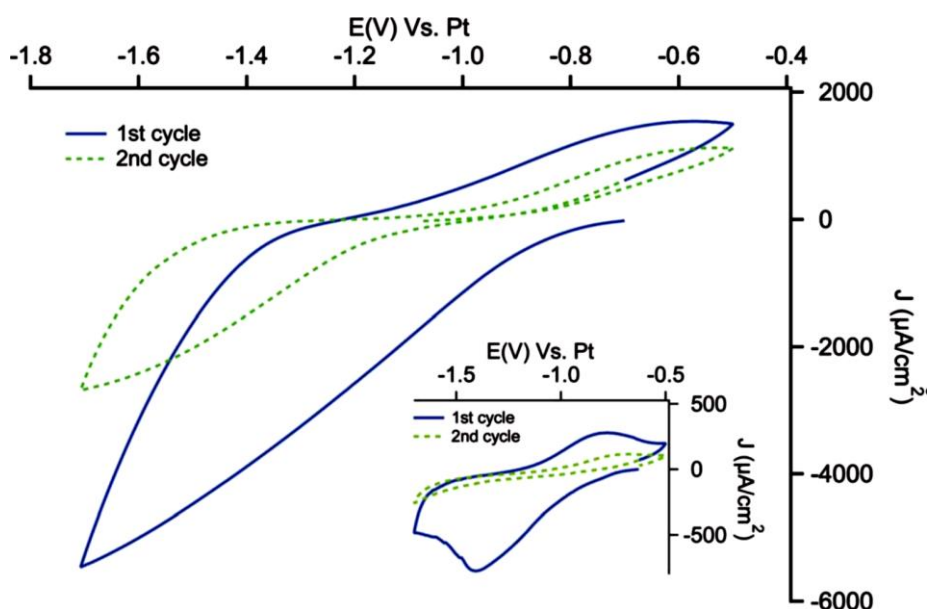

*Figure 23. Cyclic voltammograms of PSi sample modified with NBD in water/ethanol media containing 0.1 M KNO$_3$, scan rate: 100 mV s$^{?-1}$. Inset: cyclic voltammograms of PSi sample modified with NBD in water/ethanol media containing 0.1 M KNO$_3$, scan rate: 10 mV s$^{-1}$.*

The common accepted mechanism for the reduction of nitrophenyl moieties in protic medium involves the formation of the redox reversible couple nitrous/hydroxylamine (NO/NHOH), followed by the irreversible amination of the hydroxylamine group [124] [125]. According to this mechanism, the wave visible in the first cathodic scan can be related both to the formation of hydroxylamine intermediate and the irreversible reduction to NH$_2$ groups, while the anodic wave indicates the formation of the nitrous group from the hydroxylamine intermediate.

In the second cycle, the extent of the reduction peak is significantly diminished, while the anodic peak is still visible, indicating that the reduction of nitro to amino group is not complete: about 90% of the electro-responsive groups is estimated to be converted in $NH_2$, considering the voltammetric charges involved in reduction and oxidation processes. The aminophenyl modified samples were then submitted to electropolymerisation in ACN solution containing perchloric acid (0.1 M) and aniline (0.1 M). As a comparison, pristine PSi samples were modified by direct electrochemical polymerisation. As can be seen in Figure 24, the first scan of polymerisation is characterised by an increase of the anodic current for both samples, attributable to the oxidation of the aniline monomer to anilinium radical cation, which starts the polymerisation process [126] [127], indicating that the aminophenyl layer does not have a blocking effect on aniline oxidation. In the subsequent cycles, a couple of redox peaks are visible only for PSi modified with an aminophenyl layer (see magnification in inset of Figure 24 (b)).

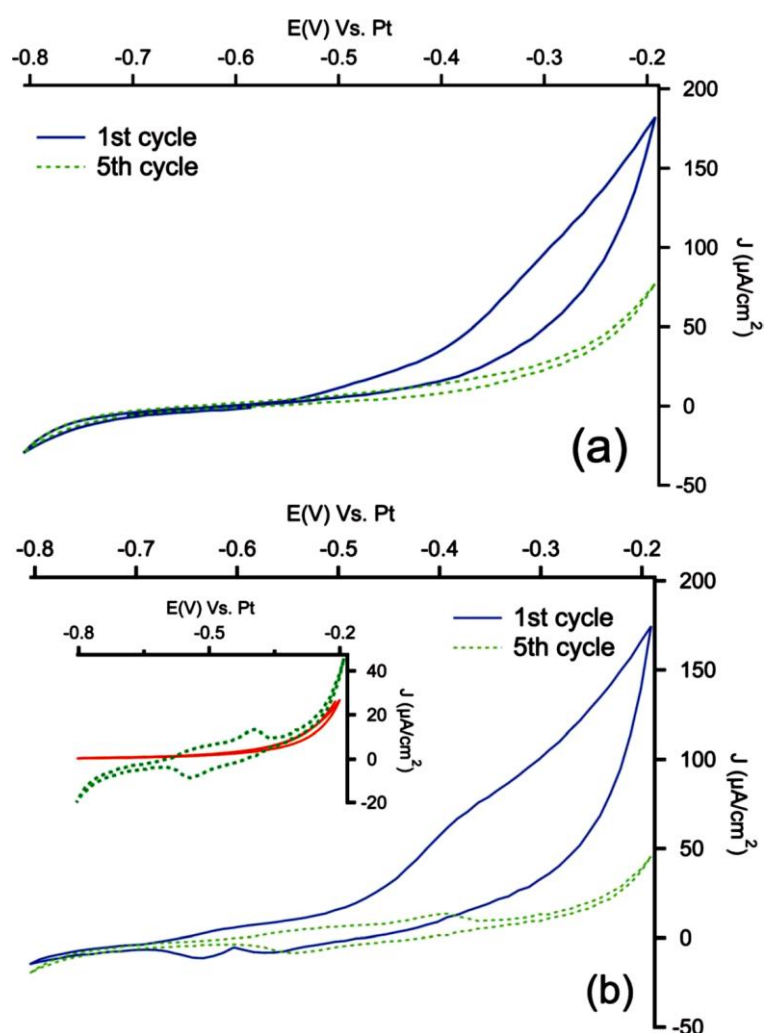

Figure 24. Cyclic voltammetry response recorded during electro- polymerisation of aniline in 0.1 M HClO4 + 0.1 M aniline in acetonitrile media on PSi (a) and Ar/PSi (b) at the scan rate of 30 mV s$^{-1}$. Inset shows a magnification of 5th cycle, compared with the corresponding response of Ar/PSi in monomer-free solution (red curve).

In order to check if these peaks could still be the response of residuals NO/NHOH groups of the reduced NBD layer in the acidic medium, cyclic voltammetries have been performed in a monomer-free solution before the electropolymerisation. As can be seen, no appreciable signals can be detected in the polymerisation range. The two peaks detected during the electropolymerisation can be related to the redox transitions of PANI from leucoemeraldine to emeraldine and from emeraldine to pernigraniline [128]. In the case of electropolymerisation on pristine PSi samples, the redox couples are not visible neither in the fifth cycle, indicating that the polymerisation process is more effective on the aminophenyl modified electrode. Similar behaviour has been reported for gold and carbon based electrodes modified with PANI with and without an aminophenyl layer [129] [130]. The polymerisation of PANI is a self-catalytic head-to-tail process: the presence of aminophenyl layers grafted onto the PSi can promote the oxidative radicalic polymerisation process and, due to the similarity of the organic layer to aniline, it can offer a large number of starting points for the aniline polymerisation, allowing us to obtain a more strongly adherent coating [131]. The lower efficiency of polymerisation observed with bare PSi may be due to concentration gradients between the porous layer and the bulk of the solution during the process. The concentration of aniline inside the pores (i.e. the concentration of reactant) is lowered by the formation of the anilinium radical cation. The monomer must then diffuse from the bulk to the porous layer, adding a mass-transfer resistance to the process. When the underlayer is present, the anilinium radicals may instead react with grafted phenylamine, which does not present diffusion limitations. The presence of an electroactive PANI layer on the PANI/Ar/PSi can be evidenced by cyclic voltammetries in monomer-free solutions. Figure 25 shows the voltammograms recorded in ACN solution containing $HClO_4$ 0.1 M: the typical peaks related to doping and undoping of protons and anions in the polymeric film, as well as the transformation between different forms of PANI, are visible at high values of scan rate [132].
*Figure 25. Cyclic voltammetries performed on PANI/Ar/PSi electrodes in ACN monomer-free solutions containing HClO$_4$ 0.1 M at different scan rates.*

## 3.3   Optical characterisation

The optical characterisation of the porous silicon impregnated with polymers has been performed by using reflectivity spectra.

The reflectivity spectrum of a thin layer of porous silicon corresponds physically to a thin layer with plane and parallel faces. The thin-layer interference pattern derived from this material, also called Fabry-Pérot fringes, are due to an overlapping of reflection from the surface of the porous silicon with the one coming from the interface between porous silicon and the bulk. A typical example of a porous silicon reflectivity spectrum is shown in red in Figure 26. For wavelengths shorter than about 400 nm it is possible observe two peaks related to the bulk silicon: they will be present in every spectrum unless the presence of another material covers the sample surface. The intensity, position, and number of the fringes depends on the product of the refractive index **n** and the real thickness of the porous layer **d**, also called optical thickness.

The porous layer is seen by light as a homogenous layer (the pore diameter is about 10-20 nm while the average wavelength is 500 nm). Under that condition, the refractive index is a combination of the refractive index of the crystalline Si skeleton and the refractive index of the medium inside the pores. For a fresh sample, the air is the medium inside the pores. After the process of polymer grafting and impregnation, the refractive index within the pores is that of the polymer, so the total refractive index changes and the shape and the position of the interference fringes is modified.

To measure the reflectivity spectrum, a UV-Vis-NIR spectrophotometer has been used, capable to measure the optical properties as reflectivity, absorption and transmission in a range of wavelength from 180 to 2500 nm. By using a special module called URA (Universal Reflectance Accessory), the spectrophotometer allow the measure of direct reflection with an angle of incidence in the 8°-63° interval in the wavelength range of 250-2500 nm.

Functionalized PSi layers were immersed in aqueous NaOH since it is well known that the dissolution of pristine PSi after immersion in a NaOH solution takes place very quickly [133] [134]. Concentrated aqueous solutions of NaOH can be used to test the chemical resistance of our grafted samples to harsh chemical environments. We used two solutions with two different concentrations: 0.5 and 0.1 M. The samples have been left immersed in the solution twice for 10 s, and then depending on the sample resistance the immersion duration was varied from 2.5 to 5 minutes until total dissolution.

In order to characterise the improved resistance of grafted samples to alkaline etching, we monitored the optical reflectivity after each etching step. The reflectivity spectra were measured in the 250–2500 nm wavelength range. Any modification of the PSi layer will lead to a modification of its overall refractive index and then of the thin-layer interference fringes. Observing the variations in the thin-layer interference fringes amplitude and position, together with the Si reflectivity peaks, it is possible to follow the modifications of the layer with respect to initial freshly grafted PSi layer. In Figure 26, as a reference, we show the effect on a pristine PSi layer of a 10 s dipping in a 0.5M NaOH aqueous solution. The red curve represents the porous silicon reflectivity, and the typical Fabry-Pérot fringes related to the thin-layer interferences are clearly visible for wavelengths longer than about 400 nm. After 10 s dipping (blue curve), as expected, the interference fringes are no longer visible due to the almost complete dissolution of the porous layer.
*Figure 26. Absolute reflectivityspectrum of the pristine Psi in red vs the absolute reflectivity spectrum of PSi after total dissolution inNaOH 0.5 M aqueous solution.*

The behaviour of grafted PSi samples is markedly different. During the initial dipping, it was possible to visibly observe that the portion of the PSi layer outside the nitrobenzene-grafted area (that is the external surface region near the bulk Si—porosified Si separation border) was immediately dissolved while the grafted area appeared unmodified throughout the process. To characterise the resistance of the layers, as for the pristine PSi layer, we used optical reflectivity measurements. For all samples, we measured the reflectivity of both pristine and grafted layers, as a reference. In

Figure 27, we show the evolution of the reflectivity as a function of the total dipping time for a PSi sample whose grafting has been realized using the potentiostatic method. The pristine and freshly grafted samples are also shown (red and black curves, respectively). The decreased reflectivity of the Si-related double peak and the interference fringes displacement demonstrate both the Si covering and the modification of the average refractive index of the porous layer induced by the nitrobenzene grafting.
*Figure 27. Reflectivity evolution of PSi grafted by the potentiostatic method with 4-NBD. The sample has been immersed in NaOH 0.5 M . The spectra are vertically shifted with respect each other by a 30% offset. The bottom spectrum has no vertical shift.*

We observe that the shape of the spectra in Figure 27, remains unmodified after about 5 min of NaOH dipping. For comparison, it is worth noting that the portion of PSi layer not covered by diazonium was immediately dissolved in the alkaline bath while the covered area stayed stable for much longer in the process. After 10 min, the reflectivity started to change and, after 15 min dipping, no trace of the porous layer is observed, indicating a full PSi dissolution. The potentiostatic grafting method has then clearly improved the chemical resistance of the PSi layer, that remains unmodified for two order of magnitude longer times with respect the pristine porous silicon.

Using the same scheme, we studied the behaviour of samples whose grafting has been performed by cyclic voltammetry. Since the PSi coverage depends on the number of CV cycles (as shown in Figure 19), we tested the chemical resistance of the samples grafted using different numbers of CV cycles.

In Figure 28, we show the evolution of the reflectivity spectra of a PSi grafted with 5 CV cycles as a function of the dipping time. We observe a significant increase by a factor of 2 to 4 with respect the functionalization in the potentiostatic regime: after 20 min etch, while clearly partially degraded, the thin film interference fringes were still visible, indicating that the porous layer was still present.
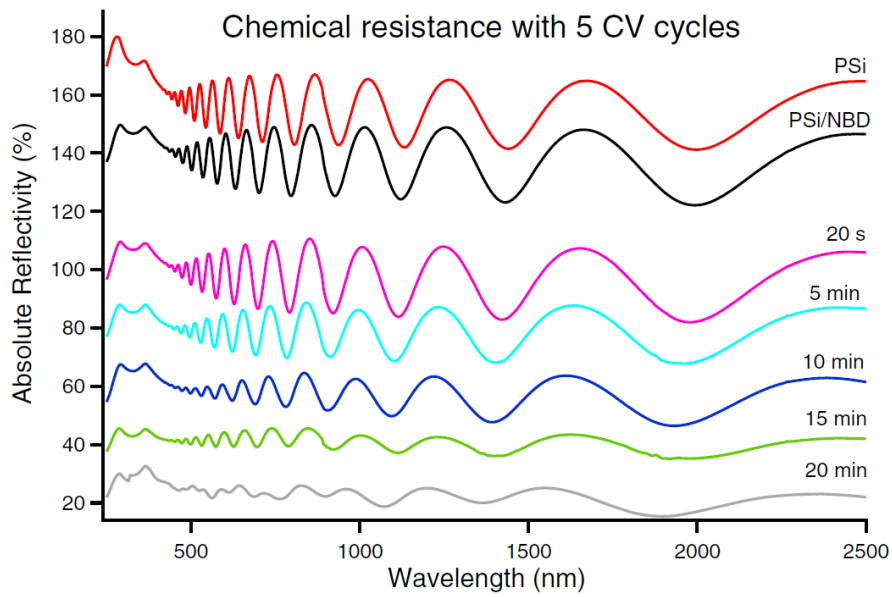

*Figure 28. Reflectivity evolution of PSi grafted with five CV cycles. The sample has been immersed in NaOH 0.5 M . The spectra are vertically shifted with respect each other by a 30% offset. The bottom spectrum has no vertical shift.*

We performed the chemical resistance test on samples modified with different numbers of CV cycles since, as shown in Figure 19, after five CV cycles the reduction peak is still present. For less than five CV cycles, the chemical resistance, while still higher than that observed for potentiostatic grafted samples, was decreased with respect to that obtained for the sample of

Figure 28. For more than five CV cycles, instead, an increase of the chemical resistance is observed. In Figure 29, we show the evolution of the reflectivity spectra for a PSi sample grafted with eight CV cycles.
*Figure 29. Reflectivity evolution of PSi grafted with eight CV cycles. The sample has been immersed in NaOH 0.5 M . The spectra are vertically shifted with respect each other by a 30% offset. The bottom spectrum has no vertical shift.*

In this case, it is clear that there is a significant improvement with respect to the five CV cycles grafting: after 38 min, the PSi structure is only slightly modified. Further increasing the number of cycles does not significantly improve the chemical resistance, even if the reduction peak is visible up to the 12th cycle.

The number and the position of the fringes depend on the optical thickness of the porous layer. The refractive index of PSi depends on the porosity and, once that is fixed, on the pores content. When filling the pores, the air is progressively replaced by the polymer, changing then the overall refractive index of the porous matrix. It is worth noting that since the pore size is more than one order of magnitude smaller than the shortest wavelength in the spectrum, therefore all light scattering effects can be neglected.

The comparison of the spectra in Figure 30 (a) and (b) is interesting in view of understanding the different behaviours induced in the PANI and PSi composite, with and without the presence of the aryl under-layer. Figure 30 (a) shows the PSi layer where PANI has been inserted without the aryl under-layer. It is evident that the PANI/PSi composite (green curve) does not show major differences with respect to the PSi reflectivity without PANI (black curve). This is not the same when the aryl layer is inserted before PANI, as shown in Figure 30 (b): PANI/Ar/PSi (green curve) shows a reflectivity spectrum where the thin layer interference fringes are significantly modified with respect to the pristine PSi layer (black curve).
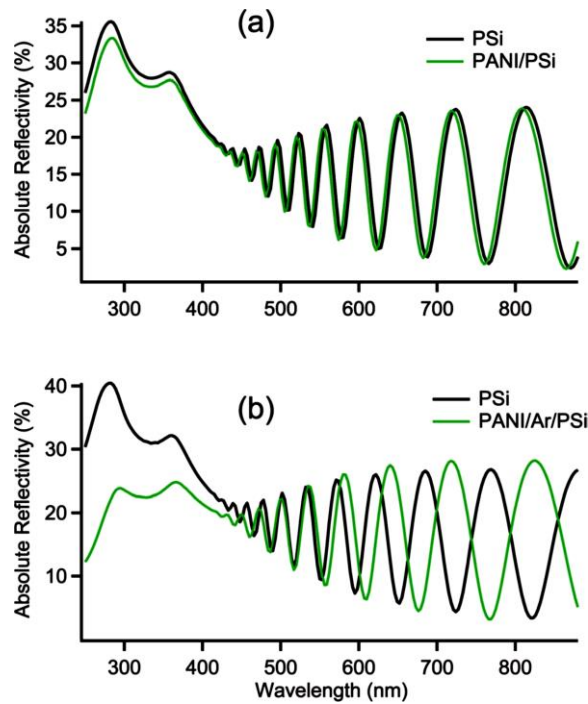

*Figure 30. Reflectivity spectra: PSi and PANI/PSi (a); PSi and PANI/Ar/ PSi (b).*

The presence of PANI also induces a significant reduction of the Si doublet peak, since the silicon surface is progressively covered. The displacement of the fringes is indicative of a modification of the optical thickness of the layer. Since the absence of features of a double layer excludes the possibility of a thick PANI layer on the external PSi surface, the modification of the periodicity of the fringes can only be attributed to the presence of PANI within the pores, demonstrating the effectiveness of the filling process.

Figure 31 shows the spectra of crystalline silicon, crystalline silicon with PANI and crystalline silicon with Ar/PANI: no interference fringes can be observed, while changes in the reflectivity are present in the region of wavelengths shorter than 1100 nm, which can be attributed to the optical response of PANI. We analysed the reflectivity data in Figure 30 and Figure 31, modelling the presence of PANI within the porous layer.
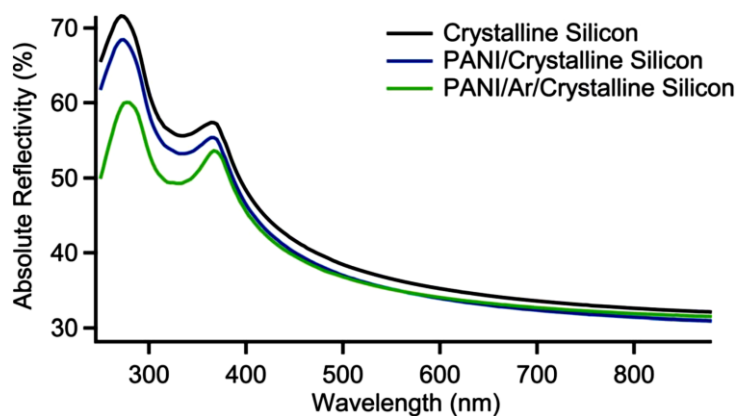

*Figure 31. Absolute reflectivity of the cristalline silicon vs. PANI/Ar/Si and PANI/Si.*

Our analyses show that PANI is present in the whole layer both with and without the aryl underlayer, even if there is a gradient in the PANI concentration along the sample's thickness. The gradient is expected as it is common in all thin pores filling processes. In our case, for PANI/Ar/PSi, the concentration gradient is such that the bottom concentration can be estimated to be about one third of the surface concentration. On a homogeneous layer fitting, i.e. without considering concentration gradients, the PANI filling can be evaluated as filling about 80% of the pores inner volume. This also can be expected since, given the dendritic structure of the PSi pores, it is difficult for the aniline to fill every available volume portion. In summary, the reflectivity data fitting confirm the presence of the PANI in the whole structure and that a concentration gradient is also found. A comparison of the PANI/PSi results with the analysis of the reflectivity spectra of PANI/Ar/PSi shows a reduction of the PANI content when the underlayer is not present. Although a reliable quantitative evaluation of the PANI content is difficult with only the simulation of reflectivity spectra, a rough estimate suggests that the amount of PANI in PANI/PSi is less than two times that in the corresponding PANI/Ar/PSi. These results confirm that for aminophenyl-modified PSi the polymerisation process is more effective.

## 3.4  Spectral dependence of the photocurrent

By using the low pass filter described in Material and Methods in section 2.4.1, we performed photocurrent measurements. The light has been provided by a full spectrum lamp. The filters have been placed under the light and the corresponding photocurrent generated has been recorded. The results are shown in Figure 32. The p–n junction between the organic layer and PSi improves the light absorption in the visible range compared to the empty porous silicon (Figure 32 (a)). The absolute white-light photocurrent was also higher for the hybrid junction. The PANI/Ar/PSi samples show a

marked photosensitivity, higher with respect to pristine PSi by one order of magnitude. A different behaviour can be observed with PANI/PSi (Figure 32 (b)): the photoresponse (yellow curve) is comparable to that of the pristine porous silicon; in the range between 400 nm and 800 nm the sample does not show the increase in absorbance obtained with PANI/Ar/PSi.

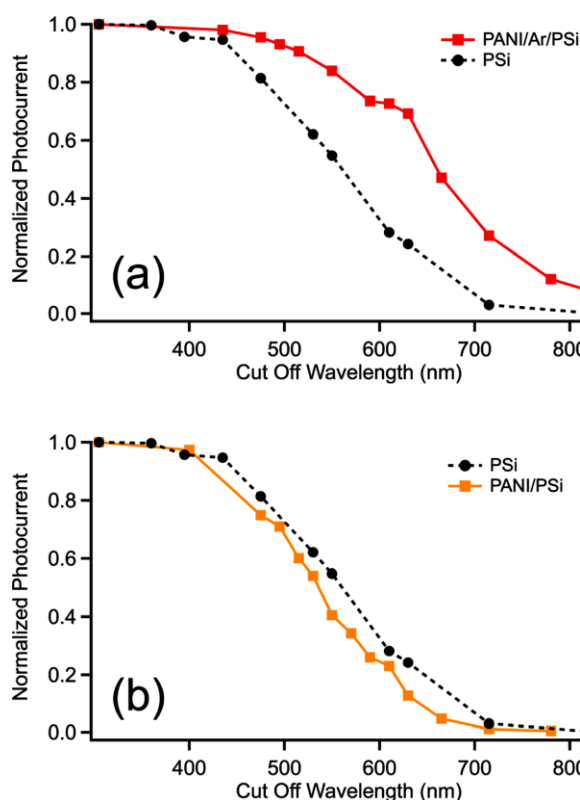

*Figure 32. Comparison between normalized photocurrents of PSi and PANI/Ar/PSi (a), and PANI/PSi (b).*

These results show the role of the underlayer in the functionalization of the hybrid structure. As a matter of fact, without underlayer it appears that the photocarrier generation contribution from the PANI content of the pore is negligible, while it is significant when the PANI impregnation is performed in a sample where the underlayer has been previously deposited. This may be due to the inefficiency of the interfacial junction between the organic and the inorganic components, without the aminophenyl layer, that possibly impedes the photocarriers generated within the polymer from crossing the interface.

In order to study the effect of the different operative conditions, as the scan rate and the number of cycles of electropolymerisationon the photocurrent, different PANI/Ar/PSi samples have been prepared using different scan rates of electropolymerisation, maintaining the same conditions of preparation for the underlayer.

Figure 33 shows the second polymerisation cycle at different scan rate: as can be seen the current intensity of redox peaks of PANI polymerisation are visible and they increase with the scan rate, indicating that PANI growth occurs under each examined condition.

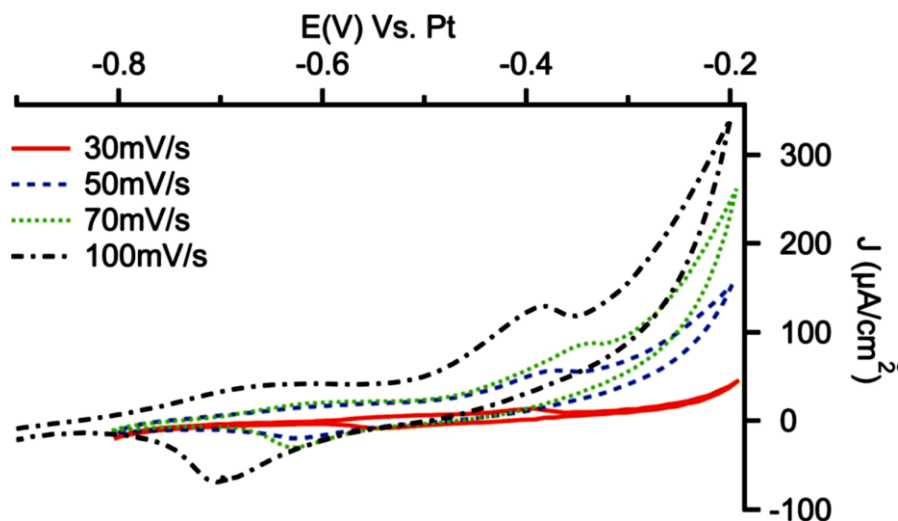

*Figure 33. Cyclic voltammograms (2nd cycle) recorded during electro-polymerisation of aniline in 0.1 M HClO$_4$ + 0.1 M aniline in acetonitrile media on PSi electrode after NBD reduction at the scan rate of 30, 50, 70 and 100 mV s$^{-1}$.*

Figure 34 (a) and (b) show photocurrents obtained for PANI/Ar/PSi samples with different scan rates and number of voltammetric cycles. As can be seen, differences in the absolute value of the photocurrent are clearly visible: in particular, the photocurrent increases when the scan rate decreases and, when the scan rate is fixed the photocurrent increases with the number of cycles. It is well known that characteristics such as morphology, conductivity and rate of the polyaniline growth are strongly dependent on the operating conditions [135].

When potentiodynamic electrodeposition is used, the scan rate can play an important role. The growth mechanism of PANI may occur via three different dimerization paths (i.e., head-to-head, head-to-tail, and tail to-tail), as well as competitive degradation reactions [135]. Depending on the scan rate, the formation of polyaniline can be controlled by the fastest reaction (i.e., head-to-tail polymerisation) or by the secondary reactions (e.g., tail-to-tail, head-to head polymerisations, degradation reactions) [118]. In our case, further issues complicate the process, since the polymerisation occurs in a porous structure, where diffusion effects overlap the kinetic aspects. The number of CV cycles also affects the overall efficiency of the system, as shown in Figure 34 (b) for a series of samples prepared with a scan rate of 30 mV s$^{-1}$, which increases the number of CV cycles.
*Figure 34. Photocurrent registered for different scan rate (a) and different number of CV (b).*

## 3.5   Photoconductive AFM results

In this study, PC-AFM, a recent noteworthy method for nanoscale characterisation of photovoltaic elements, was used for direct measurements of the photocurrent generation properties at the nanoscale with respect to standard millimetre-size areas. The effects of changes in the current intensity were observed. The PC-AFM analysis described hereafter has been performed on a PSi sample impregnated with eumelanin with the methodology described in [63].

In PC-AFM, the tip used plays a fundamental role. The tip needs to be coated to be conductive and that significantly increases the tip radius. The porous silicon pores used for all the experiments described earlier were too small to allow detection of any local pore-dependent current given the difficulty in selecting a specific region of interest. For those reasons, we fabricate PSi layers whose pores were significantly larger, reaching about 60nm diameter. The samples were prepared using the

Electrochemical NanoLithography technique, developed in the PoroSiLab, that allows to control the distribution and density of pores by an electrochemical etching process that leaves small indentation on the Si surface acrting as seeds for the nucleation of the pores. In Figure 35 is shown the top view SEM image of the sample prepared with this technique that we used in our PC-AFM experiment. The advantage of these samples is that thanks to the larger pores geometry the photoconductive behaviour showed a significantly longer temporal stability (several weeks as compared to a couple of days), a parameter that is obviously extremely relevant for the PC-AFM experiments.

*Figure 35. SEM image of the new sample with large pores.*

The first step of the analysis consists in finding what is the most appropriate tip for photoconductive measurements, that can at the same time resolve the porous structure. In Figure 36 an AFM topographic image of a PSi sample is shown similar to the one shown in Figure 35. The tip used in this case, an ARROW-CONT-Pt, with a Platinum coating has tip radius of <30nm. This tip has been used in contact mode and the pore feature were not visible. The image shows the impossibility to distinguish individual pores.

60
*Figure 36. AFM image of the sample by using contact mode. First test.*

For those reasons we decided to use an alternative tip as shown in Figure 37: an OPUS 240 AC-NA. This tip has a radius of <7 nm and is made for tapping mode scans in case of photoconductive material with particularly hard surface. By using the Opus tip, it has been possible to resolve the porous structure with the AFM (Figure 38).

*Figure 37. AFM tip used for better resolving the porous structure of the PSi.*

*Figure 38. AFM images of the surface of the PSi sample for 50 total scans of imaging.*

By monitoring the scanning along the surface, we noticed the tendency of the pores in the image to blur. Making more tests, as the one shown in Figure 39, we discovered that the PSi surface is able to

relatively quickly deteriorate the probe tip, creating as a result the difficulty to acquire more than one image of a small area at a time.

*Figure 39. AFM image test of the sample surface for a total image acquisition.*

The images in Figure 40 are obtained by focusing on a smaller area of 10 μm x 10 μm and subsequently zooming in an area of 200 nm x 200 nm. As it is possible observe, the pores are not plugged and this confirms that the filling procedure doesn't modify the top surface of the PSi.

*Figure 40. AFM images of the PSi/eumelanin sample (left) and a smaller area (right).*

By zooming further, topography and current maps have been performed after the procedure of laser beam focusing. From the images in Figure 41 (a) and (b), it is possible to observe some well-defined pores. In Figure 41 (c) and (d) the current map is shown, and the corresponding current is recorded in proximity to the pore. The two curves are aligned in order to demonstrate that the current peak registered corresponds to the hole in the topographic image.
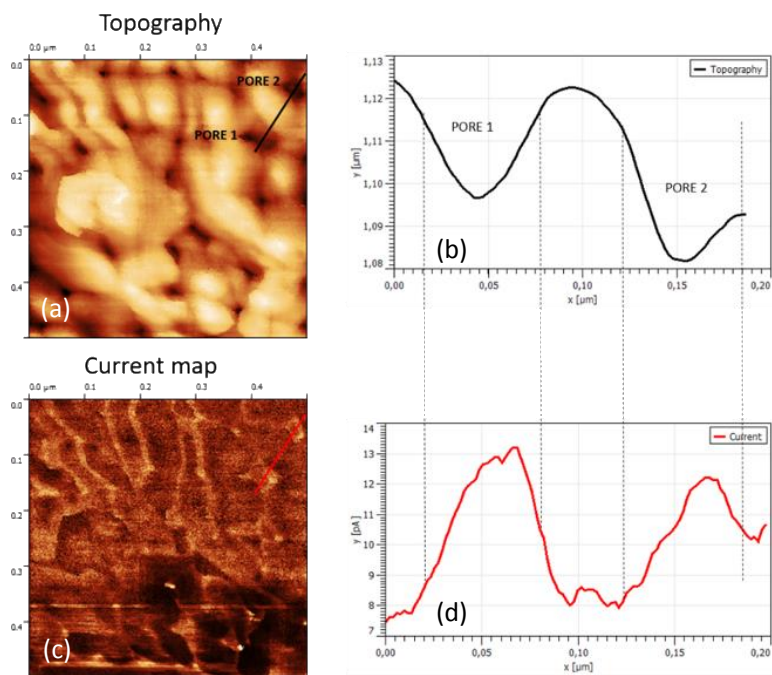

*Figure 41. PC-AFM image and current map with the respective line scan showing dimension and current registered.*

*Figure 42. PC-AFM image of an area of 500nmx500nm and enlarged image of one single pores of one single pore and the respective current map.*

Zooming further into the topographic images, as shown in Figure 42, it is possible to notice how the current response is enhanced inside the pore (yellow in current map). PC-AFM is useful to identify spots of current generation inside the pores. This application on porous silicon needs to be improved further by using different kinds of tips and measurement procedures.

Porous silicon will play an important role in the "Analysis for Innovators" Innovate UK project, which addresses measurement challenges for industries, where it will be used to test the resistance of coated tips for AFM to deterioration, and in general for atom probe microscopy and to determine the response in photocurrent generation and topography capability.

## 3.6 Optical lithography

Optical lithography is an important part in semiconductor and manufacturing technology. It refers to a lithographic process that uses visible or ultraviolet light to form patterns onto a semiconductor surface by using a mask that reacts with the light: the mask can be a photomask or a light sensitive resist distributed onto the surface called a photoresist. The photoresist needs a developer that is usually an alkaline solution, usually containing NaOH, to form the desired pattern on the surface after the illumination [136]. This solution, as mentioned before, cannot be used for PSi because it causes a dissolution of the silicon matrix. Since the NBD makes PSi resistant to dissolution induced even by harsh alkaline solutions, this means that it is possible to perform optical lithography on porous silicon without its degradation after NBD functionalisation of the porous layers. The SEM image in Figure 43 after the NBD functionalization shows that that the pores are not plugged even after 12 CV cycles, where the diazonium reduction peak is almost not present anymore.

*Figure 43. SEM image of porous silicon grafted sample (top view)*

The lithography process was performed using a positive photoresist in which the portion exposed to the light become soluble to the developer solution. In the first step the photoresist AZ5214E has been spin coated on the porous silicon sample surface. To allow the total evaporation of the solvent contained in the photoresist, the sample has been softly baked making it photosensitive. The device matrix applied to the sample is a $50 \times 50$ $\mu m^2$ pattern of metallic squares. This metal mask was patterned on the sample exposing the resist-coated surface to UV light of high intensity. After the UV exposure the photoresist has been developed in a solution 1:1 volume containing deionized water and

a sodium based basic AZ developer and removed by using a lift-off technique. After the metallic pads pattern was successfully obtained on the sample surface, the contacts were deposited by electron beam evaporation of a 5 nm thick layer of of Ti followed by a 90 nm layer of Au. This allows to perform some basic electrical resistance measurements on the porous silicon sample and to compare the electrical behaviour of the grafted PSi with the pristine PSi.

In Figure 44 (a), it is possible to observe in the right side of the optical microscope image residual photoresist removal after a bath in acetone on silicon bulk and the pattern on the porous region delimited by the O-ring (used to define the region of the sample where the Psi is being generated) by the dashed line. In Figure 44 (b), a SEM image of the final gold contacts deposited on the sample surface is shown.

(a)                                        (b)
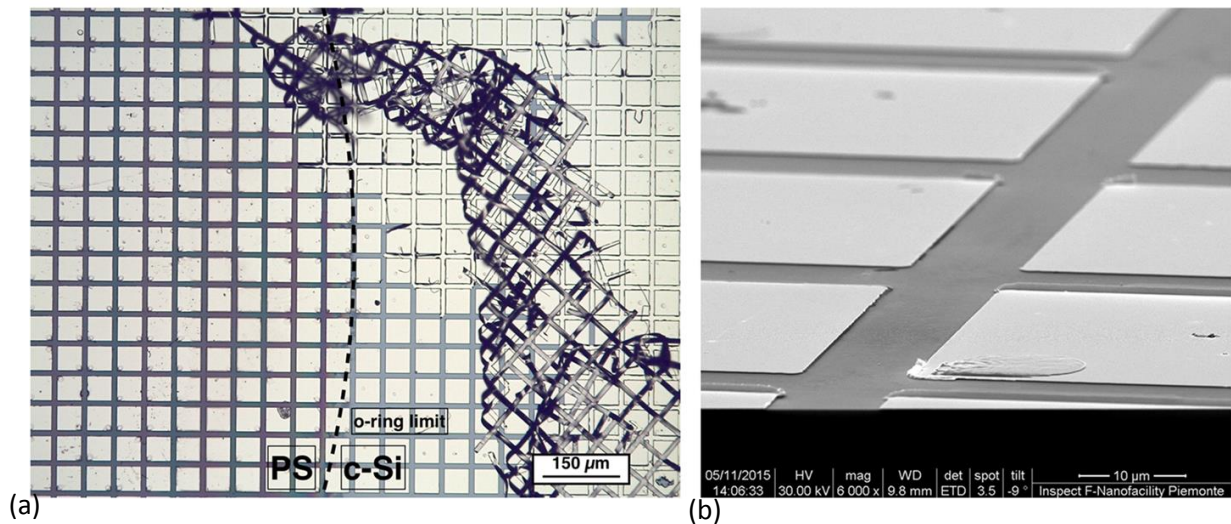

*Figure 44. Optical image (a) and SEM image (b) of the grid after deposition.*

The effectiveness of the NBD deposition in protecting the Psi layer from the NaOH based alkaline developing solution needed for photolithographic process is evidenced by the optical and SEM images shown in Figure 44.

In Figure 45 (a) (cross section) and (b) (top view), is possible to notice how the porous structure is fully preserved as well the open pores in the top view.
*Figure 45. SEM images after litographic process from the PSi/NBD cross section (a) and surface(b).*

This demonstrates that the NBD functionalization of the porous matrix by using cyclic voltammetry effectively protects the PSi from dissolution by contact with chemical alkaline solutions.

Further I-V characterisation of the PSi (black curve) and the PSi grafted with NBD (green curve) shown in Figure 46 shows that there are no significant differences in the current response behaviour between the two samples apart from a slight variation of the resistance in the grafted sample. This shift can be due to small variations in the porous silicon layer.

*Figure 46. I-V characteristic curve of PSi vs the PSi grafted with 15 cycles of NBD.*

## 3.7 Summary

The PSi grafted and impregnated with conducting polymer has been characterised by using different techniques. All these techniques show consistent results and help to explain what is happening to the sample and at the interface between the two materials. The samples response to harsh chemical

agents changes dramatically, becoming significantly more resistant after the NBD grafting. Moreover, the pores are not plugged, meaning that it is possible to further proceed to PANI grafting, as we discussed, and also that this opens the way to possible uses of the grafted samples in electronic devices directly or with further functionalization (e.g. for sensors) without having to deal with the issue of porous matrix dissolution.

Characterisation of hybrid materials always poses significant challenges due to the significant difference in physical and chemical properties of organic and inorganic materials. In this study, we approached the structural characterisation of these kind of materials by mass spectrometry. Given the growing interest in mass spectrometry and in its capability to analyse the components of organic compounds in term of molecular fragments from buried interfaces and from macroporous materials, we explored the use of the secondary ion mass spectrometry (SIMS) technique on Si-polymer hybrid samples, and the results of this study will be presented in the next chapter.

However, to analyse buried interfaces in multilayer samples, or interfaces between organic and inorganic materials with SIMS, the first mandatory step is to obtain a clean cross section in-situ by using a focused ion beam mounted on a SIMS instrument. This step is difficult to calibrate when using organic/inorganic hybrids, given the huge differences in the properties of these two types of materials.

The first challenge for these studies by SIMS is finding two types of materials that can act as a proxy for a hybrid material system. For this reason, due to the nanoscale nature of the PSi/polymer structures, which would initially be disproportionally complex to understand due to difficulties in the data interpretation, a preliminary study on a similar hybrid system having a larger scale, that can mimic the porous silicon system, is necessary. For this reason, we used a microchannel plate filled with two different well-known polymers as a reference material. This structure will be used as reference for enabling the development of a protocol suitable for the study of hybrid heterojunctions in smaller scales, as in the case for PSi. As we will see in the next chapter, the identification of the best measurement parameters is far from straightforward, and basic issues related to the degradation of the organic material have to be dealt with. The SIMS-based work for this thesis has been done under the international 3DMetChemIT project [137].

# 4  Microporous hybrid material experimental results

In this chapter I will present the work published in the papers:

- Tiddia, M.; Seah, M. P.; Shard, A. G.; Mula, G.; Havelund, R.; Gilmore, I. S. Argon Cluster Cleaning of Ga + FIB-Milled Sections of Organic and Hybrid Materials. *Surf. Interface Anal.* **2018**, DOI: 10.1002/sia.6522.

- Tiddia, M.; Seah, M. P.; Mihara, I.; Trindade, G.F.; Kollmer, F.; Roberts, C.; Hague, R.; Mula, G.; Gilmore, I; Havelund, R. FIB-SIMS for Hybrid Materials – Cleaning the FIB Damaged Organic Material with Argon Gas Cluster Ions. **(submitted)**

## 4.1    Challenges to be addressed

Chemical characterisation at organic-inorganic interfaces is challenging, in particular if these are buried. SIMS is well suited for this purpose, but accessing buried interfaces is often difficult. Standard depth profiling as described in Chapter 2 is problematic because the inorganic phases sputter more slowly that the organic phases. An alternative approach is the use of FIB milling to prepare section for SIMS analysis.

SIMS has been used for many years with FIB to provide analysis through very local sections of materials to depths of many micrometres [138–142] . The FIB sections are generally made using a focussed Ga$^+$ ion beam provided with the smallest spot sizes, [139] [143] with reasonable beam currents and sputtering rates. Ga$^+$ ions during the milling remove material and are implanted in the surface of the remaining material and they can be easily detected by the SIMS. Excellent examples of the method for inorganic samples have been shown by Whitby et al, [141] Schneider et al [142] and many others, but in case of organic-inorganic hybrid materials, the FIB-SIMS analysis becomes strongly challenging. This is mainly because the FIB damages the organic material. Methods are needed to minimize or remove the FIB damage for successful FIB-SIMS analysis. A recent work by Iida et al [144] reports how an organic material that has been damaged by a FIB can be removed by using Ar GCIB sputtering [144] (notice that, in this chapter, Ar refers to the chemical element argon as opposed to Aryl used in chapter 3). Here, we present a study of FIB-SIMS using three different FIB sources Ga$^+$, Bi and Bi$_3^+$. First, a simple sample of polystyrene and PMMA spin coated on silicon and as sheets has been analyzed and subsequently an inorganic-organic test device has been developed, consisting of a regular pattern of a polymer,

either PMMA or PS, and silicon. This is used to study and optimize the FIB-SIMS parameters and the FIB damage cleanup procedure.

We focus the attention on two categories of samples; the first group is used to study implantation effects on flat surfaces and the second group is used to study the behaviour in FIB-milled sectioning. The first category consisted of high purity Goodfellow PS sheets, 1.2 mm thick, used to study the effect of the $Ga^+$ ion angle of incidence. The second category of samples is inorganic-organic structures suitable as archetypes for analysis. These samples were made by pressing either PS or (PMMA) into the MCP surface [84] and then annealing it at 210 °C under load in a vacuum oven for 5 hours as described in section2.2.2. The MCP is made from sintered glass tubes, with a hole diameter of 10 μm, in a hexagonal array tilted at 12° to the MCP surface normal. The hot pressing fills these tubes with polymer. The inner surfaces of the tubes have a surface coating to enhance the electron multiplication required for its original application. Studies were also made of unfilled MCPs. The glass of the MCP occupies 37% of the volume with the remainder either unfilled (vacuum) or filled with polymer.

## 4.2   Experimental setup design

To prepare a cross section for analysis, a Ga FIB is used with an energy of 30 keV (20 nA) to mill out a crater size of 120 μm in the *x*-direction and 80 μm in the *y*-direction (see Table1 for the beam parameters). The milling is monitored using the $Bi_3^{2+}$ beam with a field of view of 200 μm by 200 μm containing 512 × 512 pixels. This configuration is shown in Figure 47 (a). The crater wall prepared for SIMS imaging is the top wall, closest to the $Ga^+$ source, at an angle of approximately 45° to the MCP surface normal. The beam follows a sawtooth raster pattern with the scan direction being from left to right in the images, starting from the bottom and moving to the top in each scan as showed in Figure 47 (b).
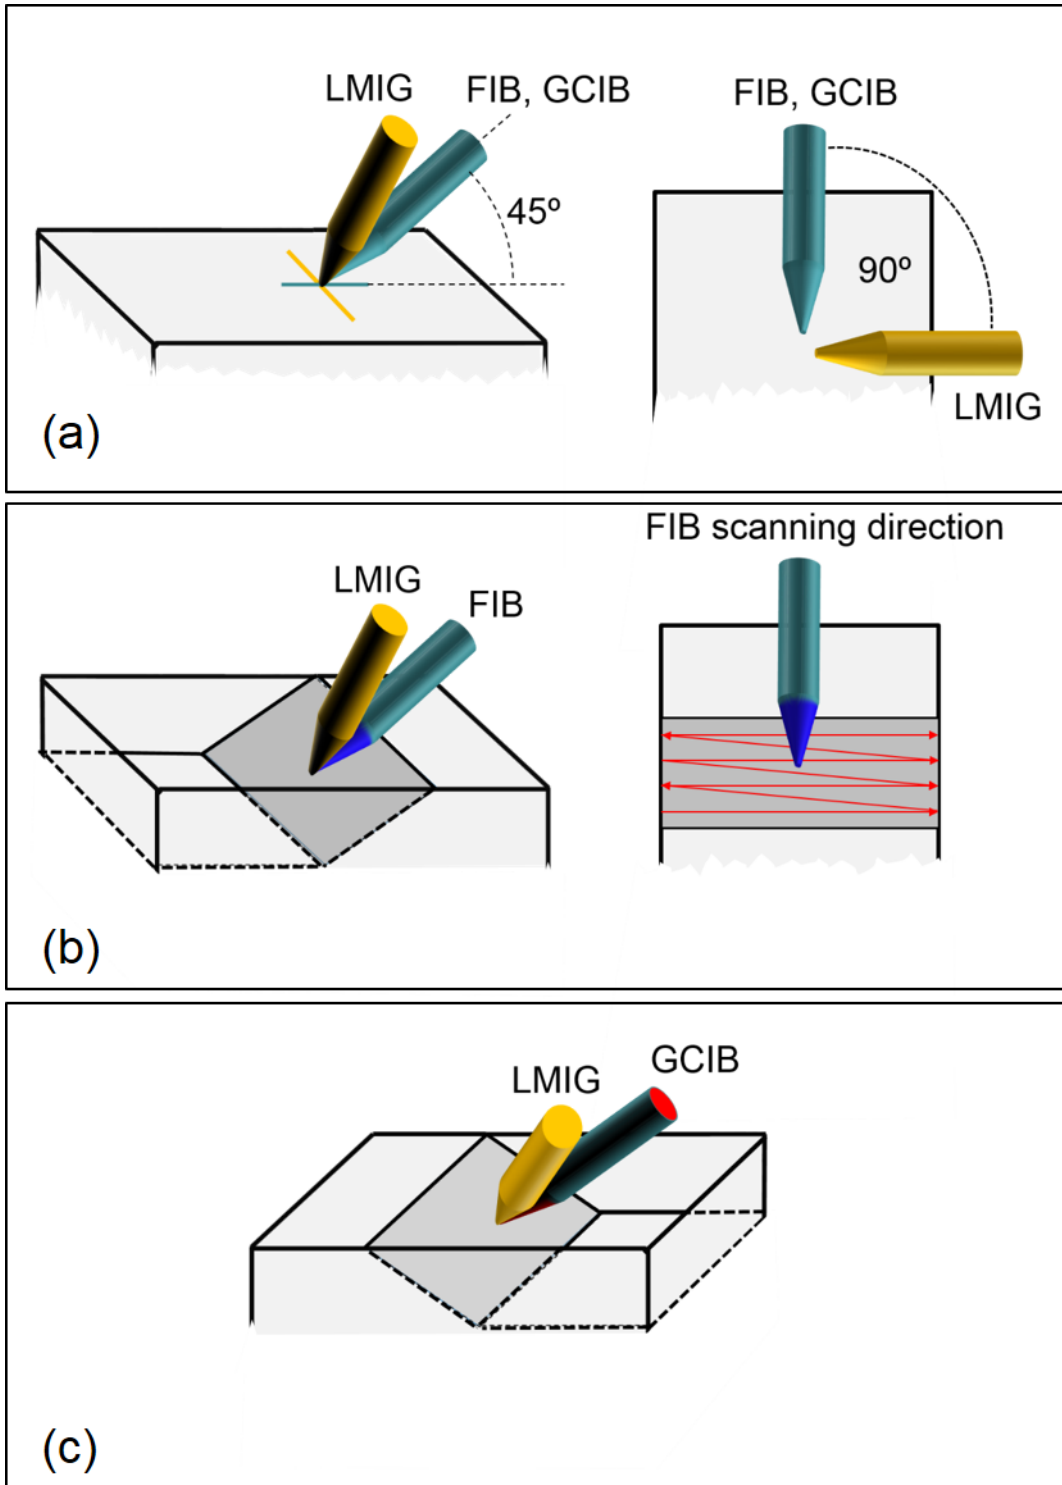

*Figure 47. Schematic representation of the FIB-ToF-SIMS geometry. (a) FIB and LMIG (b) Sample milling and FIB scan direction. (c) Cleaning process by using the GCIB with a 180° rotation of the sample.*

| Focused Ion Beam Parameters | | | | | | | |
| --- | --- | --- | --- | --- | --- | --- | --- |
| Type | Energy | Crater size | Current | Pixel | FOV | Milling pass | Dwell time |
| Ga+ | 30 keV | 120 µm × 80 µm | 20 nA | 512 x 512 | 300 µm × 300 µm | 1, 2, 3 | 25 ms/pixel |

*Table 1. FIB parameters*

To optimize the lateral resolution of the secondary ion image, after the cleaning procedure, the sample is further rotated 90°. In that orientation, the $Bi_3^{2+}$ beam is normal to the FIB section surface to give the optimal lateral resolution.

The removal of the damaged layer on the FIB section by Ar GCIB is performed with the sample rotated by 180° (see Figure 47 (c)). This clean-up procedure leads to the recovery of the characteristic organic secondary ion signals from the milled wall (at approximately 45°, as we shall see later). The Ar GCIB was an $Ar_{2500}^+$ beam at 10 keV (4 eV/atom) with a beam current of 6 nA and was rastered over a 500 µm × 500 µm area. Secondary ion images are recorded during the Ar GCIB clean-up to follow the recovery of the correct organic signals using the $Bi_3^{2+}$ beam with a current of 0.02 pA.

A schematic of this sample with a FIB-milled surface is shown in Figure 48 (a). To reduce damage and re-deposition on the final cross section wall, the FIB-milling is made with a raster that starts at the lower left in Figure 48 (a) and finishes at the top right of the final sectional surface to be studied. Section surfaces are made with 1, 2 and 3 passes of the full raster to extend the depth of the cut but, in the present context, we see no differences between these final surfaces except for the depth over which they extend.

All of the FIB-milled sections discussed in this work relate to the hybrid MCP samples. An imaginary slice through the FIB-milled surface is shown in Figure 48 (b) rotated clockwise through 45°, so that the Ga+ beam is now vertical. The implanted Ga+ ions may be deposited to a certain depth which may be calculated using the SRIM program [145].

SRIM calculations were carried out in collaboration with Dr Martin Seah at the National Physical Laboratory. Used directly, SRIM allows the implantation of many ions but each new ion is into the same pure undamaged polymer. In the continuum process of milling the section, this deposition will have occurred many times, associated with the overlayer removal, so that the SRIM calculations below, whilst correct for small doses, need modification for high doses.

In practice, the cutting may be associated with some roughening. Long wavelength roughening is not a problem, but the development of cone-like structures would require much more extensive cleaning

by the Ar$^+$ GCIB. Figure 48 (b) shows, schematically, these two possibilities. In much of the discussion that follows it is assumed that the polymer surface is smooth. If the surface were to be rough as shown with forward facing cones, their shape would be difficult to measure at the scale required using either scanning electron microscopy or atomic force microscopy.

(a)

(b)
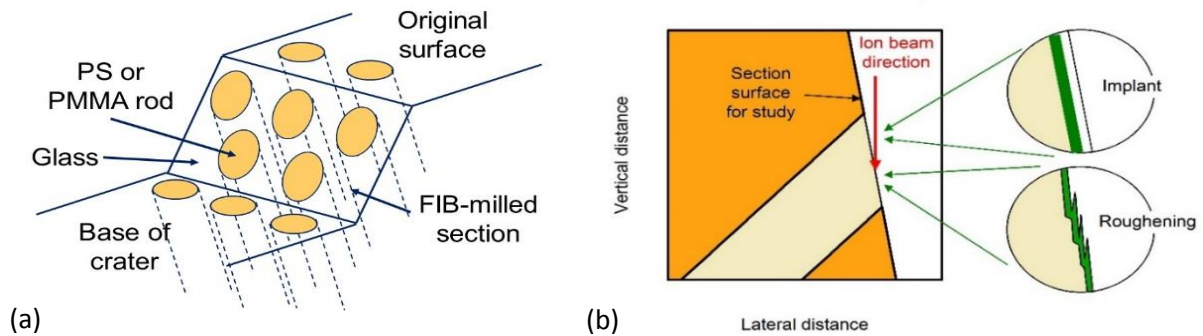

*Figure 48. Schematic of polymer rods (light yellow) set in the glass structure (orangey-yellow in (b)) of the microchannel plate, (a) showing the general arrangement of the FIB-milled section and (b) with enlarged schematics of an implanted layer (upper circle) and a roughened surface (lower circle). In (b), the Ga$^+$ ion beam direction is shown by the red arrow and the final exposed section surface is inclined at 80° to the horizontal.*

Figure 49 shows SRIM [145] computations for the low dose implantation of 30 keV Ga$^+$ ions into pure PS, at angles of incidence from 0° to 80°. We see a profile that is well described by a Gaussian distribution, whose mean depth and standard deviation reduce as the angle of incidence rises. Knock-ons and displaced C and H atoms are also computed and occupy the region up to this distribution.

As a result of the continuous sputtering and removal of material, Ga atoms and damage will already be in place at the shallower depths, i.e. to the left of the distribution. It is therefore reasonable that the effective damage and implant depth is given by the sum of the mean depth plus a factor times the standard deviation of the Gaussian function. The size of this factor will depend on the level of damage, that is critical.
*Figure 49. SRIM computations for the implantation depth distributions, each for 5000 trajectories of 30 keV Ga+ ions into pure PS for many angles of incidence, θ.*

## 4.3    Application to pure polymer

Many profiles of the Ga$^+$ implanted flat PS surfaces were recorded for Ga$^+$, C$_7$H$_7^+$ and other positive secondary ions for different conditions. Example profiles are shown in Figure 50 for an implanted dose of 85 Ga$^+$ ions/nm$^2$ into PS surfaces at 0°, 60° and 80° incidence angles. The C$_7$H$_7^+$ secondary ions are taken to be indicative of relatively undamaged material.

*Figure 50. Measured depth profiles for Ga$^+$ and C$_7$H$_7^+$ secondary ions from samples of PS implanted with 85 Ga$^+$ ions/nm$^2$ at 30 keV as a function of 10 keV Ar$_{2500}$ cleaning dose at 45° incidence angle. The colour scheme is the same as Figure 51 with black, orange and purple for 0°, 60° and 80° incidence angles, respectively. The solid lines joining circles are for Ga$^+$ and the dashed lines joining triangles for C$_7$H$_7^+$ ions.*

From the data reported in Figure 50 it is possible to determine the dose needed to remove the implanted and damaged layer. We may calculate the sputtering yield of pure PS, *Y* in nm$^3$, for this condition and using the equation [146]

$$\frac{Y}{n} = \frac{B(E/An)^q}{1 + (E/An)^{(q-1)}} \qquad (1)$$

where $E$ is the $Ar^+$ GCIB of 10000 eV and $n$ is the cluster size (2500 atoms in our case). For PS, the parameters $A$, $B$ and $q$ are 2.36 eV, 0.011 $nm^3$ and 3.4, respectively. Thus, $Y$ = 37 $nm^3$. The dose to remove the $Ga^+$ and for the $C_7H_7^+$ signal to reach 50% for 0° implantation is about 60 $Ar^+$ GCIB ions/$nm^2$. This, combined with the sputtering yield of 37 $nm^3$, would remove over 2 μm of pure PS rather than the 60 nm. This high GCIB dose could be due to micro-topography or to a strongly reduced sputtering yield. We shall analyse the latter here.

The observed behaviour originates from the fact that the PS being removed is not at all pure: it is highly damaged and contains a high level of Ga atoms. Both of these effects reduce the sputtering yield. Our earlier analysis of both organic and inorganic materials [146] shows that at $E/n$ = 4, the transition from organic to inorganic results in a reduction in sputtering rate of about 1000. The present situation indicates an interim position that we need to analyse more fully.

Figure 51 shows that, at a dose of about the median of the $Ga^+$ distribution plus two times its sigma, the $C_7H_7^+$ intensity has risen significantly in each case. We compute this for a rise of the PS signal to 50%, since that gives the mean effective cleaning dose. For a pure PS spectrum, significantly more cleaning may be required but the extent of that will depend on the depth resolution obtained. We cannot calculate the effective damage depth using SRIM but the depth equal to the $Ga^+$ implant depth plus two times the standard deviation width may be calculated directly, to represent a mean cleaning dose, and this is shown in Figure 51. This depth is indicated with the symbol $Z$.

*Figure 51. Depths of the $Ga^+$ parameters from SRIM calculations at various angle of incidence in PS.*

Further measurements on PS implanted at 45° but with a much lower dose of 1.14 ions/$nm^2$ give the green circle at the low $G$ value shown in Figure 52, where the data obtained through the PS data are

indicated by the purple curve, a guide the eye based upon equation (1) with the effective bond energy related term $A$ increasing with $G$. The term $A$ starts at the value for pure PS at $G = 0$ of 2.34 eV and then increases with $\log(G)$, following an integrated exponential to a value near 9 eV at $G = 5$ at/nm$^3$.

In Figure 52 we show the measurements extracted from Figure 51 and from detailed study for poly(carbonate) (PC) of Iida et al [144] (orange line). These are shown as orange circles and are relative to a cleaning procedure performed using 20 keV $Ar_{2500}^+$ at 40° incidence. Data given as circles are for implanting and cleaning on flat polymer surfaces, whereas the square symbols are for the cleaning of FIB-milled sections for PS. The purple data are for PS surfaces implanted with 85 ions/nm$^2$, whereas the green circle is at the low dose of 1.14 ions/nm$^2$. The yellow and blue squares are for a FIB-milled sections of PS, whereas the pink-red square is for FIB-milled section of PMMA.

The solid lines are descriptions using equation (1) with the parameter $A$ increasing with $G$ as described in the text. The dashed pink curve is the estimate for PMMA. For this condition, the sputtering yield of pure PC is 60 nm$^3$ [147] [148]. The remainder of the computation is as described above. The orange curve is a guide for eyes, as is the purple curve, but in this case the $A$ value starts at 4.2 eV for pure PC.

*Figure 52. Fractional sputtering yields versus the effective Ga density*

The square symbols in Figure 52 are from FIB-milled sections of the hybrid glass and polymer samples shown in Figure 48, rather than implanted flat surfaces. Note that the slope of the FIB-milled section means that these surfaces are not cleaned with the Ar GCIB at 45° but with that beam at near normal incidence. At normal incidence, the sputtering yield is reduced by a factor ~1.8 [149] compared with that at 45°. In Figure 52, the FIB-sectioned data are for PS (yellow and blue) and PMMA (pink-red) and are all computed for the Ar GCIB normal to the local surface. The effective Ga density is calculated from

the total implanted dose, here 40900 ions/nm$^2$, divided by the total depth of the cut, here 19000 nm depth for PS and 33000 nm depth for PMMA. The total depth of the cut can be measured directly from the SIMS images. For the fractional sputtering yield, we need to determine the depth sputtered and the dose. The implant depth is calculated using SRIM [150] on the basis of no roughening and for the final surface inclined at 10° to the Ga$^+$ FIB beam, i.e. the Ga$^+$ angle of incidence is 80°. We use $Z$, which is the total depth of the mean of the SRIM-calculated implant Gaussian plus two times sigma since that represents the depth of the mean of the PS signal recovery dose. We need $Z$ rather than $W$ since, in our FIB-milled section, we cannot use the Ga$^+$ signal, dominated by signal from the FIB-milled glass area, and must use instead the signal for the PS recovery as shown. Figure 53 illustrates the recovery of different PS signals for ions with 100 <$m/z$< 150. The Ga$^+$ and other signals that arise strongly from the FIB-milled glass surface are not shown. Cleaning the glass using Ar$^+$ GCIB is significantly slower than the cleaning of the PS [147]. The calculated $Z$ values are 23.5 nm for PS and 27 nm for PMMA. It may well be that these FIB Ga$^+$ contents are significant underestimated, since the depths sputtered are probably governed by the glass region rather than the polymer filling. However, the ordinate is insensitive to $G$ in this region.

*Figure 53. Depth profile showing PS secondary ions from the sloping wall of the FIB-milled hybrid PS-glass sample as a function of the 10 keV Ar$_{2500}^+$ ion dose. Note that this beam is set nearly normal to the local surface. The profiles show the groups $C_xH_y^+$ with 8 ≤x ≤11 and 7 ≤y ≤11 as shown in the legend. The black line is a cumulative Gaussian fit with its mean at 31.5 ions/nm$^2$ and which gives the yellow square in Figure 52.*

The effect of gallium bombardment on polymer chemistry shown in Figure 52 has not been studied in detail. The mechanisms would be expected to follow the general trends observed for other types of ionising radiation [151]. Such radiation induces bond scission and the generation of both excited states and free radicals. The resulting effects depend upon their lifetimes, their mobility in the polymer and the propensity to form low molecular weight, volatile products. Cross-linking generally occurs when two radicals on adjacent chains are close enough to form a bond. In all cases, both chain scission and cross-linking occur. PS is a well-studied polymer in this regard. It is able to form a long lived, stable

benzylic radical without carbon-carbon bond scission. The radical has high mobility because of the numerous adjacent sites both within the chain and on neighbouring chains. PS therefore tends to cross-link after exposure to radiation. It has been shown that the introduction of water vapour during $Ga^+$ ion bombardment of PS maintains a high sputtering rate, presumably due to the reaction of water with radical species and the prevention of cross-linking [151].

PMMA undergoes a number of reactions resulting in the loss of volatile species and the scission of the main chain. PC is also reported to predominantly undergo chain scission following irradiation, although it is less clear that this is true under ion bombardment. Mahoney [152] classes PC as a Type I cross-linking polymer along with PS, whereas PMMA is a Type II degrading polymer involving random chain scission processes. In agreement with this, Cumpson et al [153] demonstrate that X-ray exposure during sputtering increases the sputtering rate of PMMA but not PS and PC. This latter study provides a direct comparison with PS and PMMA, showing that its behaviour under combined X-ray and argon cluster beam sputtering is close to PS.

The study by Cristaudo et al [154] also shows how changing the bonding leads to a greater effect per bond in PS than PMMA. In the analysis by Seah [155] it is shown that the $A$ value of PS changes 1.445 times faster than that for PMMA for each added monomer. As the density of the end groups (no covalent bond to the next molecule) reduces, the $A$ value increases. Equivalently, as the number of strong bonds increases, $A$ will increase. If the above factor is used to convert the purple curve for PS to one for PMMA, by reducing the total change in $A$ by this factor, we obtain the dashed pink curve that passes very close to the measured result for PMMA. This confirms the major effect of the adding or subtraction of bonds in changing these sputtering rates.

The difference between PS and PMMA in Figure 52 can also be explained in terms of the greater cross-linking propensity of PS under Ga irradiation. The relative sputtering yield of Ga-irradiated PC in the same figure is shown to be even lower than that of PS, which is not expected. This may be a result of the presence of gallium in the bombarded polymer changing the dominant mechanism of radiation damage. Gallium oxide, for example has a highly exothermic enthalpy of formation (-1089 kJ mol$^{-1}$) and the removal of oxygen from the polymer could disturb the balance between chain scission and cross linking. We note that PS contains no oxygen and that gallium does not form a stable carbide. The categorizations of Mahoney [152] and Cumpson et al [153] may thus be a rough first guide to the effects for many other polymers in Figure 52.

Measurements involving implantation on polymer surfaces have been reported occasionally in the past. Miyayama et al [156] studying polyimide (PI), show, for a dose of 100 $Ar^+$ ions/nm$^2$, that the recovery dose using 10 keV $Ar_{2500}^+$ ions is ~13$E$ ions/nm$^2$ where $E$ is the energy of the implanted $Ar^+$ ions in keV. These are similar recovery doses to those shown in Figure 53 but, of course, there are no Ga atoms to

remove. The easier removal of Ar may be offset by greater cross-linking in the PI. Similar measurements are reported by Yamamoto et al [157] for the damage caused by 1 ion/nm$^2$ of 10 keV normally incident Ar$^+$ implanted into PS. They find that there is a surface damaged layer of ~30 nm with a sputtering yield of 0.23 times of undamaged PS. This damage thickness agrees with SRIM calculations of $W$ and gives a result, in the counterpart of Figure 52 for Ar content, that is just above the purple line. It is likely that the implantation of Ga$^+$, rather than Ar$^+$ which may escape before analysis, accounts for this difference. Some very interesting data for 60 keV implantation of Bi$_3^{++}$ into PS have been given recently by Kawashima et al [158]. For a Bi$_3^{++}$ dose of 0.05 ions/nm$^2$ into PS, they show how the sputtering yield falls by a factor of 3 as the PS molecular weight reduces to 1200 Da. This low molecular weight material has a higher yield than fully polymerised PS [154] [155] and so this greater change is expected. The data for high molecular weights, when plotting versus Bi content, lie close to the purple curve, moving slowly to the left as the molecular weight reduces. These results for Ar$^+$ and Bi$_3^{++}$ indicate that our analysis in Figure 52 may be applicable for all implanted species, not just Ga$^+$.

What Figure 52 shows is that the data from the smooth surfaces and the FIB-milled sections agree, indicating that the upper simple implant model in Figure 48 is appropriate and we do not need to consider the roughening. It also shows that the cleaning requires a much greater dose than generally expected – but one that varies significantly with the organic material.

## 4.4   Application to empty MCP

Part of this work consisted of the observation of how the number of milling scans affects the milled depth and the required cleaning. By using 1, 2 and 3 milling scans, we linearly increase the Ga$^+$ beam dose. As a first step we observe, in Figure 54 (a), (b) and (c), how the milled depth develops in case of the empty MCP matrix and in Figure 54 (d), (e) and (f) the MCP matrix filled with PS. This increase of depth with dose appears to be near-linear and is very similar in the filled MCP and in the empty MCP since the sputtering of the polymer occurs at a much higher rate than the sputtering of the inorganic MCP [147].
*Figure 54. Confocal images of the unfilled and filled MCP with PS after 1 sputtering scan of 20400 Ga+ ions/nm2 (a) and (d), 2 sputtering scans of a total 40900 ions/nm² (b) and (e) and 3 sputtering scans of 61300 ions/nm²(c) and (f). In the (c) is added a description of the sample geometry after milling. Each scan starts at the bottom and moves up the image ending at the top. The Ga⁺ ion beam is incident at 45° from the top.*

## 4.5    A bit of theory

In the sputter shaping of materials, the angle dependence of the sputtering yield is critical. Wehner [159] first showed the importance of this effect in the surface topography after sputtering. In 2012, Seah [160] showed that good computations of surface form could be obtained by using a combination of Sigmund's sputtering theory [94] and the evaluations of relevant parameters by Yamamura et al [161]. Further evaluations were made by Seah [160] leading to a set of 9 equations to describe the sputtering yield and its dependence on the incidence angle, $\vartheta$.

In the present work, we sputter using 30 keV $Ga^+$, 30 keV $Bi^+$ or $Bi_3^+$, or 10 keV $Ar_{2000}^+$. In the first case, we sputter unfilled MCPs. Their geometry gives a solid fraction of 0.37 for the $SiO_2$ of the MCP.

Figure 55 shows the angle dependence of the sputtering yield for $SiO_2$ using 30 keV $Ga^+$ primary ions using Seah's equations [147]. Here the maximum yield occurs at $\vartheta_{max} = 80°$. Similar calculations for $Ga^+$ and $Bi^+$ and for energies in the range 10 keV to 50 keV give $\vartheta_{max}$ as 77° to 81° with slightly higher values for the lower mass primary ion and at the higher energies.

*Figure 55. Calculated angular dependence of the sputtering yield of SiO₂ using 30 keV Ga⁺.*

At 45° incidence to the MCP surface, the sputtering yield is 6.74 atoms/ion. In our 3 craters, we have used doses of 20400, 40900 and 61300 ions/nm$^2$ so we would expect depths of 4.8, 9.7 and 14.6 μm allowing for the 37% solid fraction. Actually, the depths measured by confocal microscopy are 13.5, 25.5 and 31 μm, some 2.4 times higher. The reason for this is that whilst the average MCP surface is at 45° to the beam, the local surface being sputtered is not at 45° to the beam. The sputtering is conducted as a raster scan where the beam has an approximately Gaussian profile with a full width at half maximum of 0.8 μm on the sample surface and the pixel-to-pixel interval is 0.156 μm. Thus, the first application of the beam at 45° to the MCP surface digs a small hole but at the next pixel, there is an increased slope on the side being sputtered, so that the yield rises and a slightly deeper hole is made and so on until the angle of the FIB-milled slope at the side of the hole is approximately $\vartheta_{max}$. It may locally increase beyond this value as a result of changes to other pixels. At 70° to the FIB-milled surface, the predicted vertical depths are 12.5, 25.1 and 37.7 μm, not very different from those observed using the confocal microscopy. The average angle of the beam to the FIB-milled surface may be less than $\vartheta_{max}$ since the sputtering takes some time to equilibrate and also the fringes of the beam are sputtering surfaces that are at lower angles, or it may be higher as discussed above. Thus, the measurements of the depth milled are consistent with the model proposed.

Note that here we have assumed an average solid fraction of 37% which would be valid if the holes were random. However, we can see in Figure 54 that the alignment of the holes means that, for the beam mid-way between the holes, the solid fraction is 100% whereas when aligned at the centres of the holes it is only 17%. This causes the unevenness observed of both the crater floor and the important back wall of the craters (see Figure 54).

Calculations of the sputter profile using 30 keV Ga$^+$ on glass, at the final edge, are shown in Figure 56.

These calculations are made with the beam orientated along the *z*-direction with columns of material along that direction and at the end, for presentation purposes the whole image is rotated 45° anticlockwise. The starred co-ordinate directions are in this rotated plane.

*Figure 56. Calculations of the developing profile for 30 keV Ga$^+$ sputtering of glass at 45° incidence. The sputtering starts at y\* = 0 and proceeds with many pulses at that position before moving 156 nm to the left and repeating the process many times. The beam profile is taken to be a Gaussian as shown, but the precise shape is not relevant.*

## 4.6    Application on the hybrid microporous system

The recovery of characteristic polymer fragment ion signals from the 45° milled wall of both PS and PMMA filled MCPs is shown as a function of the Ar GCIB sputter dose in Figure 57. The characteristic ion signal is seen to rise after a certain dose similar to that previously reported for ion and electron beam damage [158,162–164].

After FIB milling, a high $Ga^+$ signal is detected on the sloping surface and the organic signals are very weak, presumably, due to polymer crosslinking and carbonisation. The damage provided by a FIB dose of $4.08 \times 10^4$ ions/nm$^2$ was removed by approximately 10 ions/nm$^2$ 10keV $Ar_{2500}^+$ for PMMA and 60 ions/nm$^2$ for PS as shown in Figure 57. The faster recovery of the signal from PMMA is expected as this polymer is not of the type that cross-links when exposed to ionizing radiation.

In Figure 58 (a) and (b), we observe respectively a SE image of the crater obtained providing a total dose of $4.09 \times 10^4$ ions/nm$^2$ for MCP filled, respectively, with PMMA and PS. Below, in Figure 58 (c) and (d) we show the secondary ion images after the clean-up process for both filled specimens.

*Figure 57. Recovery of characteristic fragment ions from PS ($C_7H_7^+$, red) and PMMA ($C_4H_5O^+$, blue) during GCIB clean-up.*
*Figure 58. Image, using emitted electrons for the Bi3+ ion beam, of the crater of MCP filled with (a) PS and (b) PMMA. Secondary ions image overlays (c) and (d) of inorganic signal coming from MCP as Rb in green, Ga in blue with the organic signal in red coming from the characteristic fragments, respectively, as $C_7H_7^+$ for PS (c) and $C_4H_5O^+$ for PMMA (d). Note that the imaging beam is at 45° to the MCP surface but the imaging system arranges the scan to a smaller deflection in its polar direction than its azimuthal direction in order to form a true square on the surface. This can cause the left-hand vertical crater wall to appear to be sloping. Its opposite wall becomes hidden.*

Figure 59 reports the clean-up at the crater wall (by selecting a region of interest centralized in the 45° wall) by using 2 and 3 scans for the FIB milling. These craters are obtained by using the $Ga^+$ doses of 40900 ions/$nm^2$ and 61300 ions/$nm^2$. The $Ar_n^+$ GCIB dose required to recover the organic signal after FIB milling using 2 and 3 milling scans are very similar and are around 40 ions/$nm^2$.
*Figure 59. $C_7H_7^+$ fragment signal recovery for 2 milling pass per scan and 3 milling pass per scan FIB craters in the PS filled MCP.*

In cleaning the MCP we showed that a dose of 38 ions/nm$^2$ would largely clean the surface. It is shown elsewhere [165] that the sputtering yield of pure PS using 10 keV $Ar_{2500}^+$ is 21 nm$^3$. However, in sputtering the Ga-implanted PS, the yield is reduced to 0.6 nm$^3$, a reduction of 60 times so that the 38 ions/nm$^2$ is required to remove the remaining 23 nm of damaged and implanted PS [165]. If we were to overclean by a further 38 ions/nm$^2$, we should remove a further 1.4 micrometres of pure PS which would lead to blurring at the edges of included phases by significantly more than this figure since the yield rises strongly at edges. Even if one limited the overclean dose to just 10%, the spatial resolution would begin to be compromised. Different polymers are affected to different extents, so that the correct dose for both cleaning and retaining optimum spatial resolution will depend on the organic material analysed. It is, therefore, recommended to measure the signals for the organic materials anticipated in the sample and to stop the sputtering for imaging the sample at, or soon after, the signal has reached 90-95% of its final value.

## 4.7 FIB milling with $Bi^+$ and $Bi_3^+$ as alternative to $Ga^+$

Gallium is the most widely used source for FIB milling. The National Physical Laboratory is equipped with a 3D OrbiSIMS instrument with a 30 keV bismuth liquid metal ion source equipped with a Wien filter, so that mass selected direct current beams of $Bi^+$ or $Bi_3^+$ can be used instead of the Ga source. This provides an interesting possibility, since cluster beams are known to create less damage in organic materials and therefore may be more suitable for inorganic-organic materials. $Bi^+$ and $Ga^+$ have much the same effect on glass in terms of the theory given above.

Before applying the $Bi_3^+$ as a FIB on the MCP/PS, we made some tests using AFM and confocal microscopy on pure polystyrene to see the effect in terms of milling depth for same doses of ion beam. The craters made using the $Bi_3^+$ were obtained by using 1 nA current and the one made with Ga by using the standard 20 nA beam. In Figure 60 (a) and (b) it is possible observe the craters created using $Bi_3$ and Ga beam for the milling procedure.

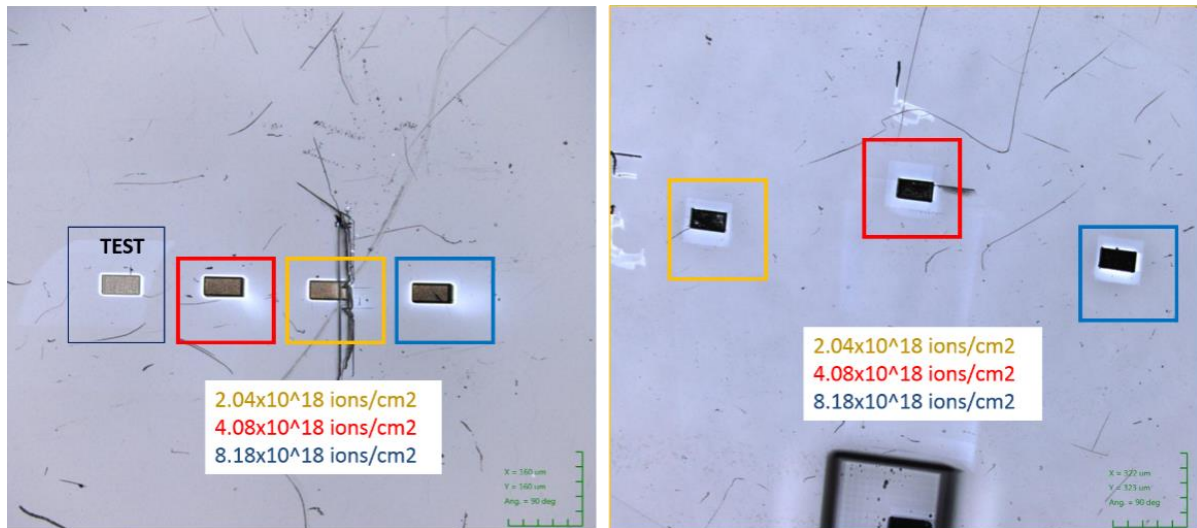

*Figure 60. Confocal images of the the craters made on by using Bi (a) and Ga (b) as ion beam.*

The confocal analysis on the crater made by using the $Bi_3^+$ beam was possible because of the limited depth of the crater. To give an idea of what is possible to achieve using the confocal analysis, a standard output is reported in Figure 61 showing the crater made using the lower dose of $Bi_3$ of 204000 ions/nm$^2$.

*Figure 61. Confocal images and x and y scan of the FIB crator depth after millin by using a $Bi_3^+$ dose of 204000 ions/nm$^2$.*

Using that method it is also possible to obtain information about the crater depth. We also use a 3D image from the AFM to confirm the depth value obtained with the confocal image reconstruction, here 1.7 μm. In Figure 62 is shown an example of image generated with the SPIP$^{TM}$ AFM software [166].

*Figure 62. AFM 3D image reconstruction of a crater made by using a Bi$_3$ dose of 204000 ions/nm$^2$.*

The respective depth calculated by SPIP software is reported in Figure 63 and is given as 1.366 μm.

*Figure 63. AFM profile of the crater in Figure 62.*

This analysis has been performed on all the craters shown in Figure 60, and the depth of every crater is determined. To study the efficiency of these sources, we use the PS filled test device. Figure 64 shows secondary electron images of craters milled using Ga+ (ToF-SIMS V) and Bi3+ (OrbiSIMS).

*Figure 64. Emitted electron image using $Bi_3^{++}$ ions in the SIMS instrument of craters formed using (a) $Ga^+$ and (b) $Bi^{3+}$ sputtering ions. The sloping face is at the top. The left wall looks sloping but is vertical and this arises since the imaging beam comes from the right and the image surface geometry is "corrected" by expanding the x-direction by a factor of 20.5.*

The results for $Bi^+$ (not shown) are very similar, but consistently poorer than those for $Ga^+$. The results for $Bi_3^+$ are very much poorer and this arises partly due to the very different angular dependence of the sputtering of cluster ions compared with monatomic ions [167] [149]. The value of $\vartheta_{max}$ for $Bi_3^+$ is much lower than for $Ga^+$ as the ions do not penetrate so far or so linearly. This leads to a slope closer to 30° with the ions no longer at the very grazing incidence into the polymer in the MCP holes.

To measure the slope of the FIB milled section of the MCP, AFM measurements has been performed.
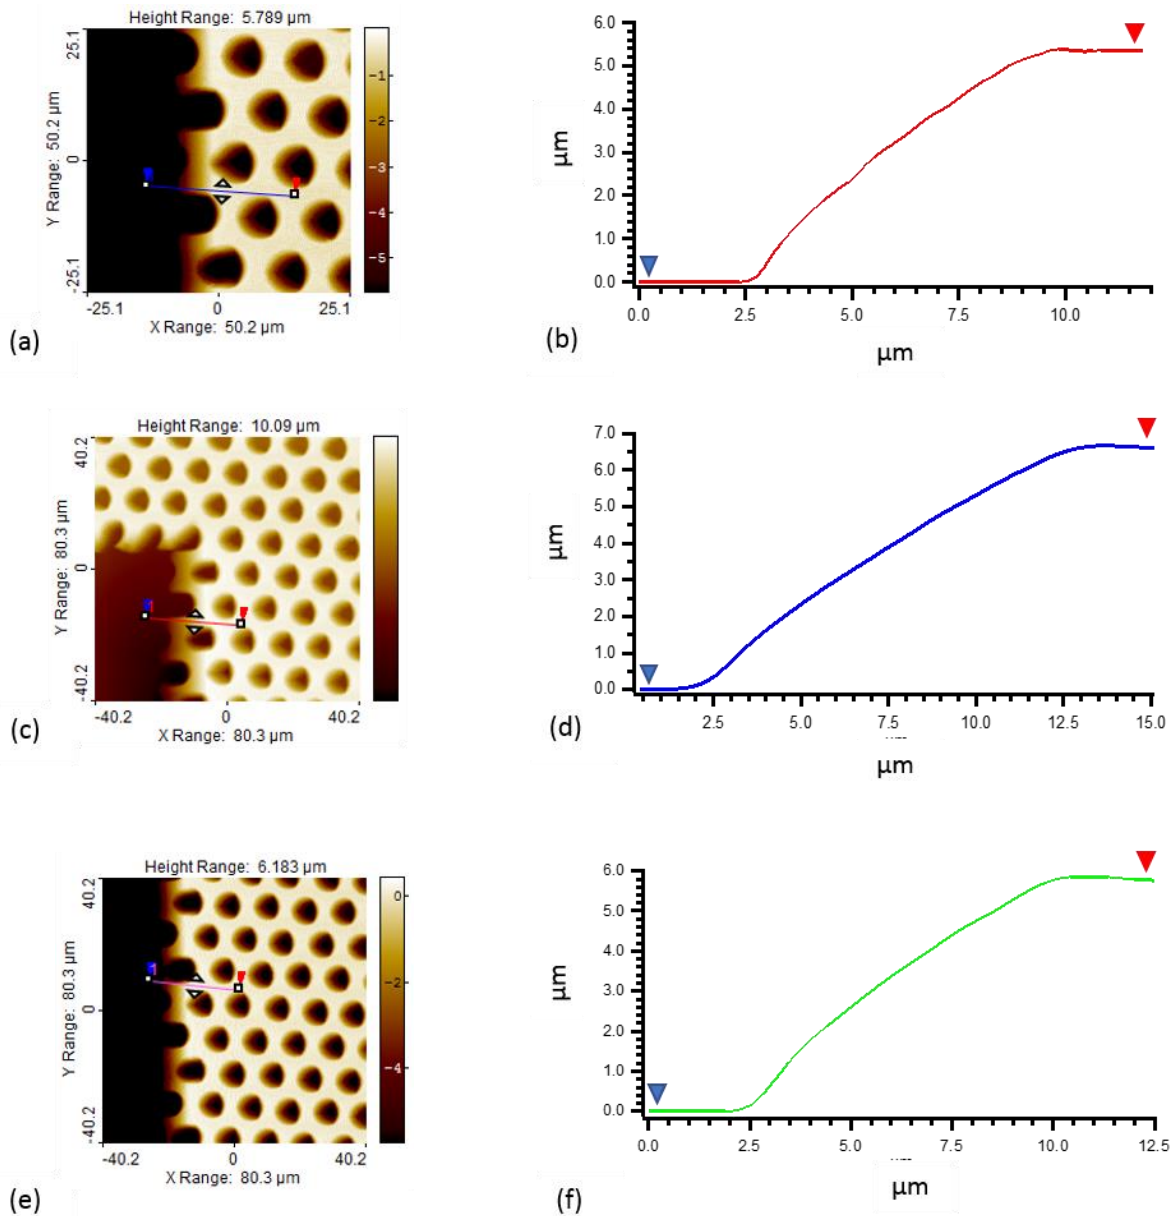

*Figure 65. AFM images of the crater edge for empty MCP milled by using a dose of 20400 (a), 40900 (c), 61300 (e) ions/nm²
and respective profile (b, d, f).*

Figure 65 shows the AFM images (a, c, d) and the measured graph (b, e, f) of the slope of the edges of the crater of the milled empty MCP samples. AFM measurements over 5 µm from the upper edge were possible before the tip lost contact in the low region. We selected the relevant region in Figure 54 (a), (b) and (c), we choose an average of several traces shown in Figure 65 (b), (d) and (f) that avoid holes and we also obtained the trace of the FIB-crater wall shown in Figure 66 (a). From that trace, the slope of the local surface due to the milling can be determined, as shown in Figure 66 (b). This slope starts at around 30° near the surface, rising eventually to around 40° further down the slope. The precise results here are affected by the enhanced sputtering around the holes but it is clear that

the final slope will be close to, but less than, 45°. The divergence from 45° is important since any polymer filling the MCP holes, for which the FIB-milled cross section is important, is shielded by the upper edge of the hole as shown in Figure 66 (a) and is sputtered at that effective angle of incidence. This region, being sputtered more rapidly than the glass of the MCP will suffer more shape distortion and be more prone to the development of roughness as this divergence increases. This allows a greater physical roughness to develop there and may explain the poor results for $Bi_3^+$.

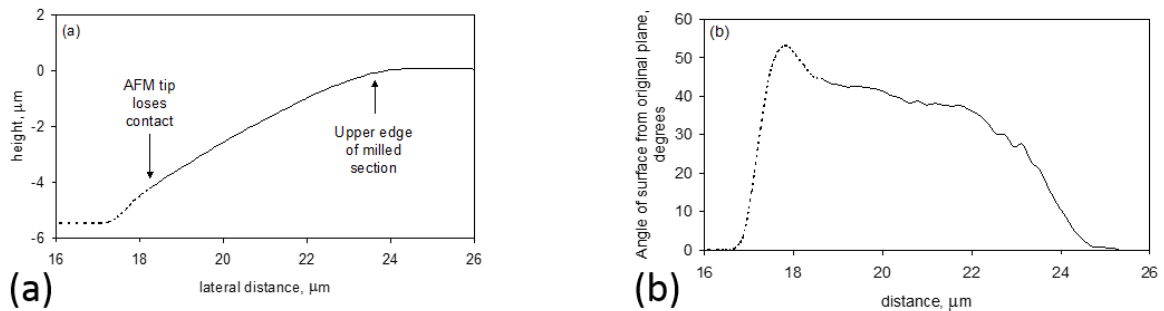

Figure 66. (a) Average trace from AFM down the slope in Figure 65, avoiding the holes and (b) the local slope of the trace as an angle of the surface from the original surface. The dashed line shows the data at the end of the trace where the tip loses contact with the sample.

Observation of the columnar structure would indicate that, at best, some 2 to 3 μm of organic material needs to be removed to clean up the surface. If this were pure polystyrene, this would need the high dose of 70 ions/nm$^2$ for 10 keV $Ar_{2500}$, but if the removal of damaged polymer is one to two orders of magnitude slower [163] [158], this figure is raised by that factor and be impossible to remove in a practical time. Cleaning of FIB section using $Bi_3^+$ is very difficult whereas that using $Ga^+$ will be much easier. Therefore, this is a negative result for $Bi_3^+$ FIB milling of organic-inorganic materials.

## 4.8 Application: Membrane Electrode Assembly and strain sensor

The FIB-TOF-SIMS methodology is evaluated for two additive manufactured devices, an encapsulated strain sensor containing silver tracks embedded in a polymeric material and a copper track on a flexible polymeric substrate created using a novel nanoparticle sintering technique.

Additive Manufacturing (AM) is at heart an interface problem where multiple layers of material are consecutively deposited to build up a physical 3D object from digital data. This interface challenge with AM will be further extended with emergence of next-generation AM that seeks to combine both structural and functional materials together in a single build. For future 3D-printed electronics, this will necessitate the contemporaneous co-deposition of both dielectric (organic) materials alongside conductive (inorganic) metallics that will create complex organic-inorganic interfaces both inter and intra layer [168].

### 4.8.1 3D inkjet-printed encapsulated strain sensor

A prototype encapsulated strain sensor containing silver tracks embedded in a polymeric material was manufactured by 3D inkjet printing of two different inks. The organic ink is made in-house and based on tri (propylene glycol) diacrylate (TPGDA) and the silver nanoparticles ink was purchased from Advanced Nano Products (SilverJet DGP-40LT-15C). Both polymer and silver layers were printed and cured/sintered contemporaneously by a LED-based UV source connected to the print-heads of a PixDro LP50 printer. More details of the ink formulations and printing process are described elsewhere [26]. The analysed volume of the sample contains, from bottom to top, 15 layers of polymer, 10 layers of silver and 5 layers of polymer. Based on previous studies, each polymer layer has approximately 10 µm and each silver layer has between 300 nm and 700 nm (see Figure 67).

(a)                                        (b)

*Figure 67. (a) Structure of the 3D inject printed strain sensor and (b) example of bio-application.*

(a)                                        (b)

The sample has been milled from the upper polymer layer following the methodology described earlier. Figure 68 (a) shows the total secondary ion images of the FIB crater after GCIB cleaning with a dose of 18.7 ions/nm$^2$. Figure 68 (b) shows a 45 μm x 45 μm map with an overlay of the signals for polymer ions and silver. After removal of the implanted gallium, the interface between the two materials is clearly distinguishable. To improve the signal to noise, an integrated intensity profile is created by summing the horizontal line scans between the regions. Owing to a tilt in the sample, a small horizontal offset is applied to each line scan to align them. Using the 16-84 % definition of profile resolution [169], the silver signal intensity across the interface (Figure 68 (c)) gives an organic-inorganic interface width as 440 nm.

*Figure 68. (a) Total ion image of the FIB crater after cleaning and several imaging acquisition, (b) secondary ion image of a selected area with an overlay of the sum of every signal coming from the polymer TPGD (in green) and from Silver (in red) and (c) interface determination by scanning the area of the polymer and the silver layers.*

Above the interface, we see a small quantity of Ag (see the area in the black rectangle in Figure 68 (c)). This could be interpreted as atomic diffusion whilst the overlayers are deposited or it could be from very small particles of Ag. Analysis of the SIMS spectra shows significant populations of $Ag_3^+$ and $Ag_5^+$ within the polymer, consistent with very small particulates, whilst none of the Ag adducts that would be expected for atomic or organically bonded Ag were observable. The populations are slightly smaller than for bulk Ag.

The milling-cleaning protocol applied to the strain sensor to study the buried interface between a track of sintered silver nanoparticles and a UV-cured polymer in a 3D inkjet-printed prototype encapsulated strain sensor shows that the two materials, after ink-jetting process, have a intermixing/diffusion at the interface.

### 4.8.2 Sintered copper tracks on a flexible polymer substrate

A sample of copper track deposited on a flexible polymeric substrate is created using a novel nanoparticle sintering technique. The device and its schematic structure are shown in Figure 69 (a) and (b). The SE image of the FIB crater is shown Figure 69 (c).

The Cu on the polymeric track is a good test case for our method, since the copper material is friable. The sample was milled with a Ga dose of 40900 ions/nm$^2$ and the characteristic PET fragment $C_8H_5O_3^+$ signal has been recovered with a GCIB dose of 12 ions/nm$^2$. In this specific case, the interface has been determined in two steps. An image for the copper distribution is acquired directly after milling (Figure 69 c) using the intense $CuO_2^+$ signal, since this signal intensity reduces under GCIB cleaning and our instrument is not equipped with an oxygen gas leak that would be used to recover the copper ion yield. Following the GCIB cleaning, the interface is re-imaged and the characteristic PET fragment, $C_8H_5O_3^+$ used to define the PET layer. As previously, average linescans (125 lines) are used to show the interface (Figure 69 d). The method shows a well-defined interface between the copper and PET layers, with no evidence of PET signal in the copper track.
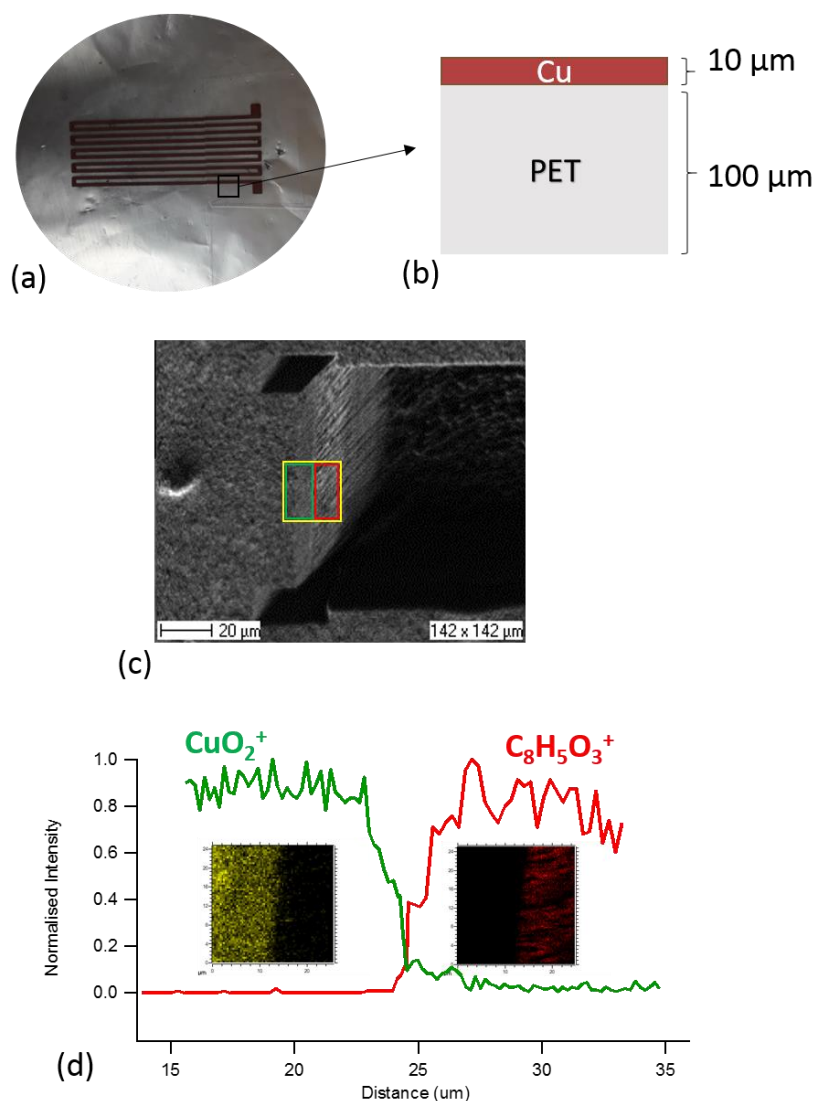

*Figure 69. FIB-TOF-SIMS analysis of copper track on PET. (a) Optical Image of the device and (b) schematic of the layer structure. (c) SE image of milled crater with the area selected for the imaging in yellow. (d) Normalized secondary ion intensity profiles (average as before) centred at the interface, for $CuO_2^+$ characteristic of the copper track (green) and $C_8H_5O_3^+$ characteristic of PET (red). Ion images of these ions are shown inset using the same colour scheme.*

## 4.9    Summary

A protocol has been developed for FIB-TOF-SIMS analysis of buried interfaces. It is shown that this is a useful method for chemical imaging of organic and inorganic interfaces.

However, the FIB milling preferentially damages organic surfaces, which limits the application for important organic-inorganic systems. The use of a GCIB clean-up cycle can remove this damage, but a systematic study was lacking. In order to address this aspect, we have developed a test device based on a microchannel plate consisting of a regular honeycomb array of tubes of 10 µm diameter. The tubes are filled with either PMMA or PS. Using this device, we were able to determine that a 10 keV

$Ar_{2500}^+$ dose on the order of 10 ions/nm$^2$ and 60 ions/nm$^2$ are required to recover the organic signal for PMMA and PS respectively.

Since $Bi_3^+$ has a higher sputtering yield than $Ga^+$ for organics, the effects of damage on organic materials may be less. We use the test-device to evaluate this for FIB milling with 30 keV $Ga^+$, $Bi^+$ and $Bi_3^+$. We found that the reverse is in fact the case, and we explain our results in terms of a theory based on the angular-dependent sputtering yield. In this theory, the angle of incidence evolves from the initial 45$^o$ geometrical angle with the fresh surface to stabilize at near $\vartheta_{max}$ as the milling proceeds. Since $\vartheta_{max}$ differs substantially between atomic (approximately grazing) and cluster projectiles (approximately 45$^o$) then the ability to successfully mill through materials with vastly different sputtering rates is affected. Therefore, our results indicate that gallium is recommended for milling organic-inorganic hybrid materials.

# 5 Conclusions and future work perspective

In this thesis, we studied the behaviour of silicon-based organic-inorganic hybrids, where their complex interfaces play a key role in the development of new technologies. The fields of interest are various and interdisciplinary. We approached these materials by studying their synthesis, characterisation and properties on the meso- and micro-scale. The inorganic matrix for the meso-scale matrix was porous silicon. The PSi samples were synthesized and grafted with polymers by means of electrochemical procedures that allow a high degree of control, thanks to the several adjustable parameters. Only in the case of Si-eumelanin hybrids, chemical methods were used. The characterisation of the PSi/PANI has also been carried out by means of electrochemical techniques as cyclic voltammetry and electrochemical impedance spectroscopy.

We were able to demonstrate that the grafting of diazonium on the inner pores surface transformed the easy-to-dissolve PSi matrix into a highly resistant material that could withstand chemical solutions as harsh as a 1M NaOH acqueous solution for about one hour without measurable modifications. This is an important result, since the feeble resistance of PSi matrices to chemical agents has been a constant problem for the use of PSi in acidic or basic environments, as is the case for biosensing applications or the fabrication process where optical lithography requires the use of corrosive solutions in the developing of the photoresist.

The strong chemical resistance shows that the diazonium is attached to the walls by stable chemical bonds. The samples chemical resistance in terms of capability to stay unmodified was tested using optical reflectivity of thin (about 1μm thick) porous layers, a technique highly sensitive to the modification of the optical properties of the layers under investigation. The AFM and SEM images of the samples show that after the diazonium grafting the pores are still not plugged, which is mandatory for the PANI grafting that follows the diazonium coverage.

After the PANI grafting, the hybrid samples ability to generate photocurrent was tested both at the macroscopic scale and at the nanoscale. The effect of the grafted polymer to improve the optical absorption and then the range where the photocurrent can be generated has been tested. We show that a p-n junction between the polymer and the porous matrix is obtained, and that the absorption of the PSi matrix is improved by the PANI grafting. At the nanoscale, to study the single-pore behaviour of the grafted porous layers we resorted to photoconductive AFM (PC-AFM), a technique able to give highly spatially resolved information on the photogeneration behaviour. Our results show that the current under illumination mainly comes from inside the pores and that the overall current intensity measured under illumination is the sum of the contribution given by every single pore.

To study the hybrids with structures at the microscale, we used a microchannel plate (MCP). This Si matrix has a number of advantages that allowed our study to be more effective. First, the micron-sized holes of the matrix are easily measurable by the FIB-SIMS technique. Second, the matrix is very regular. Third, MCP is relatively easier to fill with a polymer with respect to mesoporous PSi. Starting from these advantages, we developed a specific protocol for the analysis of organic-inorganic interfaces in MCPs filled with PS and PMMA after FIB milling.

Our protocol demonstrates how it is possible to recover the proper ion signal signature from the polymer inside the MCP pores thanks to $Ar_{2500}$clusters with energy of 4 eV per atom.

The FIB procedure has been studied on the pristine polymer to determine the doses and the limit of cross linking of the materials. Angle of incidence, dose density for milling, dose density for recovery and different beams for milling have been investigated. We demonstrate that the procedure can be also applied to other kinds of samples of a wider interest in technology and biomedical application such additive manufactured devices. The effectiveness of the method applied to different devices also proves the possibility to use the MCP as a reference sample in the study of the signal recovery. The applications on the strain sensor and on the sintered Cu tracks a polymeric substrate opens the door to further applications on different materials of interest in research and industry to determine, for instance, the homogeneity of a layer or the composition and the localization of the organic material in a hybrid composite sample.

*Future perspective*

Thanks to the results obtained in this thesis, new roads towards the understanding and optimization of the pores filling degree can be investigated. The optimal fabrication of porous structures with polymers requires that the pores are uniformly filled so that the effect of inhomogeneities can be avoided. However, the use of standard optical studies and photocurrent measurements alone do not allow a nanoscale and microscale understanding of the details of the pores filling. The next step towards a good understanding of these properties will then be the use of a combined approach where different techniques are used to determine the level of polymer filling in the pores. For example, Ellipsometry can give precise information in the depth profiling of the samples using polarized light and can be a powerful complement to the structural characterisation tools used in this thesis. Ellipsometry has been widely and successfully used for research on inhomogeneous layers, and we already performed preliminary in the filled and empty porous silicon layers. The major challenge is still the development of a reliable model for the fitting of the data, given the complexity of a nanoscale-

structured porous layer. Its development is clearly a very interesting route for further understanding of filled PSi sample.

From the structural characterisation techniques point of view, mass spectrometry where depth profiling is performed with a GCIB to clean the surface from degraded material and an LMIG for the imaging is powerful tool to obtain plane images or 3D reconstructions of the samples during profiling. Unfortunately, while for MCP the parameters have been optimized in our work, in the case of PSi the energies of the GCIB used up to now (from 5 to 20 keV) are still too high for the PSi, and further steps towards the optimisation of this process are needed. The use of a bevel cut, for instance, allowing the measure of an "enlarged" cross section of the sample may be a possible solution to this issue. The cross sectioning in situ can be made by using a ToF-SIMS equipped with a FIB. Moreover, since FIB damages every organic material and facilitates the cross linking of a wide range of polymers, the general protocol we have defined and optimized for MCP has to be further optimized for the case of mesoporous silicon.
